Abstract

This paper explores the view that a criterion of intergenerational equity serves to make choices according to ethical intuitions on a domain of relevant technological environments. In line with this view I first calibrate different criteria of intergenerational equity in the AK model of economic growth, with a given productivity parameter $A$, and then evaluate their performance by mapping the consequences of the criteria in various technological environments. The evaluation is based on the extent to which they yield social choice mappings satisfying four desirable properties. The Calvo criterion as well as sustainable discounted utilitarianism and rank-discounted utilitarianism yield sustainable growth in the AK model, the Ramsey technology and the Dasgupta-Heal-Solow-Stiglitz technology for any specifications of these technological environments.

Keywords and Phrases: Intergenerational equity.
JEL Classification Numbers: D63, D71, O41, Q01.
1 Introduction

In a series of papers (Llavador, Roemer and Silvestre, 2010, 2011, 2013; Roemer, 2011, 2013) on the ethics of intertemporal distribution in a warming planet, John Roemer and his co-authors advocate a criterion of intergenerational distribution that allows for sustainable growth. Specifically, they suggest that current wellbeing be maximized subject to the constraint that wellbeing grows at rate $g$ forever. Formally, in their sustainable growth criterion, a wellbeing stream $x = (x_1, x_2, \ldots, x_t, \ldots) \geq 0$ is selected to solve the following program (referred to as the $g$-SUS program):

$$\max \Lambda \text{ subject to } \begin{align*}
    x & \text{ being feasible and } \\
    x_t & \geq \Lambda(1 + g)^{t-1} > 0 \text{ for all } t.
\end{align*} \quad (1)$$

The exogenously specified growth rate $g$ of wellbeing is assumed to be non-negative.

In general, John Roemer supports extreme egalitarianism in the sense of maximizing the wellbeing of the worst-off individual. However, like another proponent of the maximin criterion, John Rawls (1999), Roemer is willing to depart from the maximin criterion in the case of intergenerational distribution. He writes (Roemer, 2011, p. 378):

A possible justification for choosing $g$ greater than zero is that humans want their children to be better off than they are; indeed, they are willing to sacrifice their own [wellbeing] to make this possible—or, to state this less personally (so that childless adults are included) each generation wants ‘human development’ to take place, in the sense of increasing generational [wellbeing].

His position is clarified in his response (Roemer, 2013, p. 146) to Dasgupta (2011):

No generation has an ethical license to violate the rights of future generations by choosing to discount their utility at a [high] rate, if doing so would render them worse off than their right grants them; but each generation does have the ethical permit not to enforce its own right to enjoy as much [wellbeing] as future generations. A person can voluntarily abstain for enforcing a right that applies to him, but he is not entitled to abrogate the rights of others.

---

1I use the term ‘wellbeing’ for what Roemer and his co-authors refer to as ‘welfare’. It is meant to indicate the current living situation and thus includes more than material consumption. Sentiments like altruism is, however, assumed not to be included in this indicator. In the technological environments considered in the current paper, net production is split between wellbeing and investment in reproducible capital, implying that wellbeing is measured in the same cardinal scale as capital.
This paper discusses how to capture Roemer’s position through criteria of intergenerational equity.

My discussion is not based on an axiomatic approach. Rather, I explore the view that a criterion of intergenerational equity serves to make choices according to ethical intuitions on a domain of relevant technological environments. Each technological environment combined with an initial condition gives rise to a set of feasible streams of wellbeing. The role of the criterion is, according to this view, to select the first-ranked stream according to a ranking of wellbeing streams in each set of feasible streams, thus mapping an ethically commendable social choice as a function of sets of feasible streams in a domain of relevant technological environments.

In other words, in the setting of the present paper, criteria of intergenerational equity should be interpreted in an “as-if” sense: The ethically commendable social choice is made “as-if” the choice is selected by a criterion of intergenerational equity. My approach is based on welfarism (Sen, 1979) as the selection made by a criterion depends on a fixed ranking of wellbeing streams; hence, the ranking does not change with the sets of feasible streams as determined by the technological environments. Thus, widening the domain of technological environments increases the need for a criterion to be versatile, in the sense of being able to make choices according to ethical intuitions also within the technological environments that are added when the domain is widened. I understand that this represents a form of “intuitionism” (see Rawls, 1999, p. 34, and Dasgupta, 2011, p. 478) that John Roemer may not endorse.

When the sustainable growth criterion is used in Llavador, Roemer and Silvestre (2010, 2011), it is applied in a technological environment where the wellbeing function is linearly homogeneous, and where output is a constant-returns-to-scale function of inputs that grow with rate $g$ along an efficient balanced growth path. This means that the technological environments in which Llavador, Roemer and Silvestre apply the sustainable growth criterion essentially correspond to an $AK$ model:

$$y_t = x_t + k_t = A \cdot k_{t-1}$$

for all $t \geq 1$, with $k_0 > 0$ given, where $A$ is an exogenous gross productivity parameter greater than 1, and where $k_t$ and $y_t$ denotes, respectively, reproducible capital and gross production as time $t$. In

2The analysis of the sustainable growth criterion in Llavador, Roemer and Silvestre (2010) is based on a conjectured ‘turnpike’ result, entailing that such an efficient balanced growth path is approached when the inputs initially are not in the proportions needed for efficient balanced growth. In Llavador, Roemer and Silvestre (2011) there is in addition a stock of CO$_2$ in the atmosphere which is constant along the efficient balanced growth path.
an efficient balanced growth path in the AK model, gross production, capital and wellbeing increase with a constant non-negative rate $g$ smaller than $A - 1$.

Assume now that the gross productivity parameter takes on a particular value $A^*$ and that in this technological environment it appeals to ethical intuitions that wellbeing grows by rate $g^* > 0$, where the condition $g^* < A^* - 1$ ensures that the resulting balanced growth path is feasible and efficient. In line with Roemer’s position (see the quotes above) this may correspond to a belief that each generation $t$ is willing to sacrifice some of their own wellbeing, compared to the maximum level $A^* \cdot k_{t-1} - k_{t-1}$ determined from their obligation not to violate the rights of future generations. It means that each generation chooses the same positive savings rate $s_t$ (defined as the ratio of net capital accumulation and net production) at each time $t$:

$$s_t = \frac{k_t - k_{t-1}}{y_t - k_{t-1}} = \frac{(1 + g^*)k_{t-1} - k_{t-1}}{A^* \cdot k_{t-1} - k_{t-1}} = \frac{g^*}{A^* - 1}.$$ 

In the AK model where the gross productivity parameter equals $A^*$, it turns out that an efficient balanced growth path with constant growth rate $g^*$ can be selected by a number of different criteria of intergenerational equity—in addition to the sustainable growth criterion with growth rate $g^*$, where a wellbeing stream is selected to solve the $g^*$-SUS program (1)—provided that their functional forms and the parameters are appropriately calibrated. Hence, the position that a given sustainable growth stream is a commendable ethical social choice in this particular technological environment cannot be used to evaluate the different criteria. Rather, such an evaluation can be done either by investigating the axiomatic basis—which is not the subject of the current paper—or by mapping the consequences of the different criteria in various technological environments. In the present paper I follow the latter strategy for evaluating criteria of intergenerational equity.

In Section 2 I present the criteria of intergenerational equity that I will evaluate:

- Undiscounted (or classical) utilitarianism.
- Time-discounted utilitarianism.
- Sustainable discounted utilitarianism (Asheim and Mitra, 2010).
- Rank-discounted utilitarianism (Zuber and Asheim, 2012).
- The Calvo criterion (Calvo, 1978).
- The Chichilnisky criterion (Chichilnisky, 1996).

In Section 3 I proceed to calibrate these criteria so that they all lead to a constant growth rate $g^*$ when the gross productivity parameter equals to $A^*$. Then, in accordance
with welfarism, I investigate how these criteria, as calibrated to yield \( g = g^* \) when \( A = A^* \), select optimal wellbeing streams in other technological environments: In Section 4 I consider the consequences of varying the gross productivity parameter \( A \). In Section 5 I explore the consequences of these criteria in the Ramsey technology, while in Section 6 I do the same in the Dasgupta-Heal-Solow-Stiglitz technology of capital accumulation and resource depletion.

In the concluding Section 7 I discuss the result that three of the criteria—sustainable discounted utilitarianism, rank-discounted utilitarianism and the Calvo criterion—satisfy four desirable properties in all the technological environments that I will consider. These four desirable properties are that a criterion be

- \textit{effective} in the sense of making a unique selection of a time consistent stream,
- \textit{non-wasteful} in the sense that the selected stream is efficient,
- \textit{flexible} in the sense that the growth rate of the selected stream responds to changes in the technological environment,
- \textit{sustainable} in the sense that the selected stream respect the rights of future generations by not rendering them worse off than the present generation.

In contrast, the other criteria that are treated in this paper seem not to be able to support ethical intuitions—as captured by the four properties above—across all “relevant” technological environments. Finally, I argue that the SDU criterion or the Calvo criterion might be the ones that best correspond to Roemer’s motivation for a positive growth rate \( g \), namely that the generations are willing to sacrifice their own wellbeing for the benefit of future generations.

## 2 Criteria of intergenerational equity

In the present section I present six different criteria of intergenerational equity. Together with the sustainable growth criterion with growth rate \( g^* \), they will be evaluated in various technological environments.

Let \( X \) be a set of feasible wellbeing streams for some initial condition in a given technological environment. That is, the wellbeing stream \( _1x = (x_1, x_2, \ldots) \) is feasible if and only if \( _1x \in X \). Let \( X \) be the union of \( X \) when considering the technological environments modeled in Sections 3, 4, 5 and 6, and varying the initial stocks in these
models. It follows from the assumptions made in these sections that the generalized utilitarian welfare functions introduced below, $w_T^\rho$, $w_S^\rho$ and $w_R^\rho$, are well-defined on $\mathcal{X}$.

For all elements $X$ in $\mathcal{X}$, $X$ contains only streams where wellbeing $x_t$ at each time $t$ is non-negative. Let $u : \mathbb{R}_{++} \to \mathbb{R}$ be a increasing, strictly concave and continuously differentiable function with $\lim_{x \to 0} u'(0) = \infty$ that maps positive wellbeing into transformed wellbeing (or generalized utility). In the parameterized versions of $u$ introduced in Section 3, $u$ need not be defined for zero wellbeing.

Two first criteria are standard; they were the basis for the social discounting debate which attracted much attention some years ago (Nordhaus, 2007; Weitzman, 2007; Dasgupta, 2008), triggered by the Stern (2006) review of climate change.

Undiscounted generalized utilitarianism (UU) (this particular version is “catching up” as suggested by Gale, 1967). Say that $\bar{x} \in X$ is an undiscounted generalized utilitarian (UU) optimum given the set of feasible wellbeing streams $X$ if

$$\liminf_{\tau \to \infty} \sum_{t=1}^{\tau} \left( u(x_t) - u(\bar{x}_t) \right) \geq 0 \text{ for all } \bar{x} \in X. \quad (2)$$

Time-discounted generalized utilitarianism (TDU) (see Koopmans, 1960, for an axiomatization of this criterion). Define the TDU welfare function $w_T^\rho : \mathcal{X} \to \mathbb{R}$ for the discount factor $\rho \in (0,1)$ as follows:

$$w_T^\rho(\bar{x}) = (1 - \rho) \sum_{t=1}^{\infty} \rho^{t-1} u(x_t).$$

Say that $\bar{x} \in X$ is a time-discounted generalized utilitarian (TDU) optimum given the set of feasible utility streams $X$ if

$$w_T^\rho(\bar{x}) \geq w_T^\rho(\bar{x}) \quad \text{for all } \bar{x} \in X.$$

The two next criteria capture the intuition that we should seek to assist future generations if they are worse off than us, while not having an unlimited obligation to save for their benefit if they turn out to be better off.

Sustainable discounted generalized utilitarianism (SDU) (see Asheim and Mitra, 2010, for a presentation and analysis of this criterion, including an axiomatization). Under SDU, the future is discounted if and only if the future is better off than the present. Define the SDU welfare function $w_S^\rho : \mathcal{X} \to \mathbb{R}$ for $\rho \in (0,1)$ as follows: $w_S^\rho(\bar{x}) = \ldots$
\[ \lim_{\tau \to \infty} z(1, \tau), \text{ where } z(1, \tau) \text{ is constructed as follows:} \]

\[ z(\tau, \tau) = w^T_\rho(x) \]

\[ z(\tau - 1, \tau) = \min\{(1 - \rho)u(x_{\tau - 1}) + \rho z(\tau, \tau), z(\tau, \tau)\} \]

\[ \ldots \]

\[ z(1, \tau) = \min\{(1 - \rho)u(x_1) + \rho z(2, \tau), z(2, \tau)\}. \]

Say that \( \tilde{x} \in X \) is a sustainable generalized discounted utilitarian (SDU) optimum given the set of feasible utility streams \( X \) if

\[ w^S_\rho(1 \tilde{x}) \geq w^S_\rho(1 x) \quad \text{for all } 1 \tilde{x} \in U. \]

**Rank-discounted generalized utilitarianism (RDU)** (see Zuber and Asheim, 2012, for a presentation and analysis of this criterion, including an axiomatization). Under RDU, streams are first reordered into a non-decreasing stream, so that discounting becomes according to rank, not according to time. The definition takes into account that streams like \((1, 0, 0, 0, \ldots)\), with elements of infinite rank, cannot be reordered into a non-decreasing stream. Therefore, let \( \ell(1 x) \) denote \( \lim \inf \) of \( 1 x \) if it exists (set \( \ell(1 x) = \infty \) otherwise), and let \( L(1 x) := \{ t \in \mathbb{N} \mid x_t < \ell(1 x) \} \). If \( |L(1 x)| = \infty \), then let \([1] x = (x[1], x[2], \ldots)\) be a non-decreasing reordering of all elements \( x_t \) with \( t \in L(1 x) \) (so that \( x[r] \leq x[r+1] \) for all ranks \( r \in \mathbb{N} \)). If \( |L(1 x)| < \infty \), then let \((x[1], x[2], \ldots, x[|L(1 x)|])\) be a non-decreasing reordering of all elements \( x_t \) with \( t \in L(1 x) \) (so that \( x[r] \leq x[r+1] \) for all ranks \( r \in \{1, \ldots, |L(1 x)|\} \)), and set \( x[r] = \ell(1 x) \) for all \( r > |L(1 x)| \).

Define the RDU welfare function \( w^R_\rho : X \to \mathbb{R} \) for \( \rho \in (0, 1) \) as follows:

\[ w^R_\rho(1 x) = w^T_\rho([1] x). \]

Say that \( 1 x \in X \) is a rank-discounted generalized utilitarian (RDU) optimum given the set of feasible utility streams \( X \) if

\[ w^R_\rho(1 x) \geq w^R_\rho(1 \tilde{x}) \quad \text{for all } 1 \tilde{x} \in X. \]

In the two last criteria, the TDU welfare function enters in two different ways.

The Calvo criterion (see Calvo, 1978, for a presentation and analysis of this criterion) evaluates streams according to the infimum of altruistic welfare given by the TDU.

---

\(^3\)Asheim and Mitra (2010, Section 2) use the construction presented here to establish the existence of a SDU welfare function, while using their requirements (W.1)–(W.4) as the primitive definition.
welfare function. Hence, the Calvo welfare function is defined on $X$ as follows:

$$ \inf_{t \geq 1} w^T_{\rho}(t u) . $$

Say that $1x \in X$ is a Calvo optimum if

$$ \inf_{t \geq 1} w^T_{\rho}(t x) \geq \inf_{t \geq 1} w^T_{\rho}(t \tilde{x}) \text{ for all } 1\tilde{x} \in X. $$

The Chichilnisky criterion (see Chichilnisky, 1996, for a presentation and analysis of this criterion, including an axiomatization) evaluates streams according to a convex combination of TDU welfare and the limit of transformed wellbeing:

$$(1 - \gamma)w^T_{\rho}(1x) + \gamma \lim_{t \to \infty} u(x_t),$$

where $\gamma \in (0, 1)$.

Say that $1x \in X$ is a Chichilnisky optimum if

$$(1 - \gamma)w^T_{\rho}(1x) + \gamma \lim_{t \to \infty} u(x_t) \geq (1 - \gamma)w^T_{\rho}(1\tilde{x}) + \gamma \lim_{t \to \infty} u(\tilde{x}_t) \text{ for all } 1\tilde{x} \in X,$$

or if $1x$ is a TDU optimum and $\lim_{t \to \infty} x_t = \infty$.

The UU, TDU and Chichilnisky criteria satisfy the strong Pareto principle in the sense of being sensitive to the wellbeing of each generation. The SDU and RDU criteria satisfy the strong Pareto principle on the set of non-decreasing streams, but is insensitive for changes in present wellbeing if the present is better off than the future. The Calvo criterion is sensitive to the wellbeing of a generation only if this or an earlier generation is the worst-off generation in altruistic welfare as measured by the TDU welfare function. In connection with Calvo criterion one should also note that, for a given set of feasible streams, a Pareto-efficient wellbeing stream might not be Pareto-efficient in altruistic welfare as a feasible re-allocation from one generation to the next might increase the altruistic welfare of both these generations (and any earlier generation).

The UU and RDU criteria treat generations equally by satisfying the axiom of Anonymity in the sense of being invariant to permutations of wellbeing (RDU in the strong sense of being invariant even to infinite permutations), while the remaining criteria do not treat generations equally.

The same two criteria also satisfy the Pigou-Dalton transfer principle, whereby a transfer of wellbeing from a richer to a poorer generation leads to a better wellbeing stream. This prioritarianism arises since the $u$-function that turns wellbeing into
generalized utility is strictly concave and, for RDU, also since generalized utility is
discounted according to rank by the rank-discount factor \( \rho \).\(^4\) In the other criteria, the
strict concavity of \( u \) is not sufficient for the Pigou-Dalton transfer principle to hold, as
these criteria discount generalized utility according to time. Note also that the strict concavity of \( u \) does not have the same interpretation for all criteria: In the Calvo crite-
rion the strict concavity is an expression of inequality aversion between one generation
and its successors in the “private” altruistic evaluation of the current generation. In the
other criteria, it is an expression of inequality aversion between generations in social
evaluation.

Finally, the UU, TDU and SDU induce time consistent preferences. On the other
hand, the RDU, Calvo and Chichilnisky criteria do not induce time consistent pref-
erences and, thus, each of these criteria might require choosing the best stream that
will be followed when re-applying the criterion at future points in time (this is often
referred to as \emph{sophisticated planning}).

\section{Calibration in the \( AK \) model}

The purpose of this section is to calibrate the criteria of intergenerational equity pre-
sented in Section 2 so that they all lead to a constant growth rate \( g^* \) in the \( AK \) model
when the gross productivity parameter equals \( A^* \), where \( 0 < g^* < A^* - 1 \). It is taken
as a datum that \( g = g^* \) when \( A = A^* \) appeals to ethical intuitions.

Such a calibration can be achieved by using a parameterized constant elasticity
version of the \( u \)-function that turns wellbeing \( x \) of each generation into transformed
wellbeing (or generalized utility) \( u(x)\):

\[ u(x) = \frac{x^{1-\eta}}{1-\eta}, \text{ where } \eta > 0, \]

and where the case with \( \eta = 1 \) corresponds to \( u(x) = \ln x \). The elasticity of marginal
generalized utility, \( \eta \), is a parameter of inequality aversion, and it turns out to be
constant as a consequence of the constant growth rate, \( g^* \). The strict concavity of the
\( u \)-function corresponds to a positive elasticity (\( \eta > 0 \)). It is part of the calibration
process to allow \( \eta \) to vary across the different criteria.

I will use the concept of a competitive stream to characterize the efficient balanced
growth paths in the \( AK \) model. First, note that the supporting prices \( 1p = (p_1, p_2, \ldots)\)

\(^4\)Hence, the RDU criterion combines an “absolute” Priority View with a “relative” one; see Fleurbaey (2015) and Buchak (2015).
of wellbeing is exogenously determined due to the linearity of the AK technology:

$$p_t = \left(\frac{1}{A}\right)^t$$ for all $t \geq 1$.

A feasible wellbeing stream $1_x$ is competitive with supporting prices $1\mu = (\mu_1, \mu_2, \ldots)$ of generalized utility if,

$$x_t \text{ maximizes } \mu_t u(\tilde{x}) - p_t \tilde{x} \text{ over all wellbeing levels } \tilde{x}, \text{ for all } t \geq 1.$$ 

For any feasible stream $1_x$, we have that $k_0 = \sum_{t=1}^{\tau} p_t x_t + p_\tau k_\tau$ for all $\tau \geq 1$. Hence, if a wellbeing stream $1_x$ is competitive with supporting prices $1\mu$, then

$$\sum_{t=1}^{\tau} \mu_t (u(x_t) - u(\tilde{x}_t)) \geq \sum_{t=1}^{\tau} p_t (x_t - \tilde{x}_t) \geq -p_\tau k_\tau$$

for all feasible streams $1\tilde{x}$, by the definition of competitiveness since $k_0 = \tilde{k}_0$ and $p_\tau \tilde{k}_\tau \geq 0$. Therefore, if $p_\tau k_\tau \to 0$ as $\tau \to \infty$ holds as a transversality condition, then

$$\liminf_{\tau \to \infty} \sum_{t=1}^{\tau} \mu_t (u(x_t) - u(\tilde{x}_t)) \geq 0 \quad (3)$$

for all feasible streams $1\tilde{x}$. Furthermore, by the iso-elastic form of the $u$-function with $\eta > 0$, it follows that $x_t > 0$ and $\mu_t u'(x_t) = p_t$ for all $t \geq 1$, since $u$ is continuously differentiable and strictly concave with $\lim_{x \to 0} u'(x) = \infty$. Furthermore, $1_x$ is the unique stream having property (3) for all feasible streams $1\tilde{x}$.

Note that if $\Lambda^*$ is the maximum value of program (1) in the AK model, with $A = A^*$, $g = g^* \in (0, A^* - 1)$, and initial stock $k_0$ given, then

$$\Lambda^* = (A^* - 1 - g^*) k_0$$

and

$$p_\tau k_\tau = \left(\frac{1+g^*}{A^*}\right)\tau \cdot k_0 \to 0 \text{ as } \tau \to \infty.$$ 

For the rest of this section, let $1_x$ denote the wellbeing stream defined by $x_t = \Lambda^*(1 + g^*)^{t-1}$ for all $t \geq 1$.

In the UU criterion, wellbeing is transformed through a continuous, increasing and strictly concave $u$-function and summed without discounting. The strict concavity of the $u$-function leads to a decreasing marginal generalized utility along the geometrically growing wellbeing stream which counters the effect of having a gross rate of productivity $A^*$ greater than one.

To determine how UU can select an efficient balanced growth path in the AK model, combine $x_t = \Lambda^*(1 + g^*)^{t-1}$ for all $t \geq 1$ with the requirement that $1_x$ be a competitive
stream satisfying the condition that \( \mu_t = \mu \) (constant) for all \( t \geq 1 \). The constancy of \( \mu_t \) follows by comparing (2) to (3). Since \( u \) is continuously differentiable and strictly concave with \( \lim_{x \to 0} u'(x) = \infty \) and \( \lim_{x \to \infty} u'(x) = 0 \), we must have that \( \mu u'(x_t) = p_t \) for all \( t \geq 1 \), so that

\[
(1 + g^*)^{-\eta_t} = \frac{x_{t+1}^{-\eta}}{x_t^{-\eta}} = \frac{u'(x_{t+1})}{u'(x_t)} = \frac{p_{t+1}}{p_t} = \frac{1}{A^*}
\]  

for all \( t \geq 1 \). This implies that the parameter of inequality aversion, \( \eta_U \), in the case of UU is given by:

\[
\eta_U = \frac{\ln A^*}{\ln(1 + g^*)}.
\]

Since \( 0 < \ln(1 + g^*) < \ln A^* \), we have that \( \eta_U > 1 \). Furthermore, straight-forward calculations yield that

\[
\mu = \left( (A^* - 1 - g^*)k_0 \right)^{\eta_U}.
\]

The TDU criterion discounts future generalized utility by a discount factor \( \rho \in (0, 1) \). Hence, in this criterion wellbeing is transformed through a continuous, increasing and strictly concave \( u \)-function and summed with discounting. The concavity of the \( u \)-function leads to a decreasing marginal generalized utility which together with a discount factor \( \rho \) smaller than one counters the effect of having a gross rate of productivity \( A^* \) greater than one. This means that the \( u \)-function will be less concave than in the case of UU.

To determine how TDU can select an efficient balanced growth path in the AK model, combine \( x_t = \Lambda^*(1 + g^*)^{t-1} \) for all \( t \geq 1 \) with the requirement that \( x_t \) be a competitive stream satisfying \( \mu_t = \mu \rho^{t-1} \) (decreasing) for all \( t \geq 1 \). By the properties of the \( u \)-function, we must have that \( \mu_t u'(x_t) = p_t \) for all \( t \geq 1 \), so that

\[
\rho(1 + g^*)^{-\eta_t} = \frac{\rho x_{t+1}^{-\eta}}{x_t^{-\eta}} = \frac{\rho u'(x_{t+1})}{u'(x_t)} = \frac{p_{t+1}}{p_t} = \frac{1}{A^*}
\]  

for all \( t \). This implies that the parameter of inequality aversion, \( \eta_T \), in the case of TDU is given by:

\[
\eta_T = \frac{\ln A^* + \ln \rho}{\ln(1 + g^*)}.
\]

where \( \rho \) satisfies

\[
\frac{1}{A^*} < \rho < 1.
\]

This condition implies that \( \ln A^* + \ln \rho > 0 \) to ensure that the \( u \)-function is strictly concave. Note that the \( u \)-function is less concave with discounting (i.e., \( \eta_T < \eta_U \)) as
\( \ln \rho < 0 \). In particular, if \( 1 < A^* \rho \leq (1 + g^*) \), then \( \eta_T \leq 1 \). Hence, the requirement that \( \eta_U \) be greater than 1 does not hold for \( \eta_T \). Furthermore,

\[
\mu = \frac{((A^* - 1 - g^*) k_0)^{\eta_T}}{A^*}.
\]

Also in the SDU and RDU criteria, the wellbeing \( x_t \) of each generation is transformed into generalized utility \( u(x_t) \) by an increasing, strictly concave and continuously differentiable function \( u \). Both SDU and RDU discount future generalized utility by a discount factor \( \rho \in (0, 1) \), as long as the future is better off than the present, thereby trading-off current sacrifice and future gain. Hence, if wellbeing is perfectly correlated with time, these criteria work as TDU. The important difference is that, in the criteria of SDU and RDU, the future is discounted because priority is given to the worse off earlier generations. However, if the present is better off than the future, then priority shifts to the future. In this case, future generalized utility is not discounted, implying that zero relative weight is assigned to present wellbeing.

In the present case of the wellbeing stream \( 1x \) defined by \( x_t = \Lambda^*(1 + g^*)^t \) for all \( t \geq 0 \), wellbeing is perfectly correlated with time. Hence, SDU and RDU yields the same result as TDU: The stream \( 1x \) is the unique SDU optimum and the unique RDU optimum if the \( u \)-function is parameterized by \( \eta_S = \eta_R = \eta_T \) as given by eq. (6).

To formally demonstrate that \( 1x \) is a SDU when the \( u \) function is parameterized in this way, note first that it follows from Asheim and Mitra (2010, Proposition 2(i)) that TDU welfare \( w_T(1\tilde{x}) \) is always as great as SDU welfare \( w_S^P(1\tilde{x}) \) for any wellbeing stream \( 1\tilde{x} \), where the welfare functions \( w_T^P \) and \( w_S^P \) are defined in Appendix A. However, as stated in Asheim and Mitra (2010, Proposition 2(ii)) \( w_S^P(1x^+) = w_T^P(1x^+) \) for a non-decreasing stream \( 1x^+ \). Finally, it follows from the fact that \( 1x \) is the unique TDU optimum that \( w_T^P(1x) > w_T^P(1\tilde{x}) \) for any feasible stream \( 1\tilde{x} \) not identical to \( 1x \). Combining these results yields:

\[
w_S^P(1x) = w_T^P(1x) > w_T^P(1\tilde{x}) \geq w_S^P(1\tilde{x})
\]

for any feasible stream \( 1\tilde{x} \) not identical to \( 1x \), thereby establishing that \( 1x \) is the unique SDU optimum if the \( u \)-function is parameterized by \( \eta_S = \eta_T \) as given by eq. (6).

The corresponding result for RDU optimality can be established by adapting Zuber and Asheim (2012, Proposition 10) to the AK model.

Turn next to the Calvo criterion which maximizes the infimum of TDU welfare of all generations. It applies the maximin criterion, not on the wellbeing stream \( 1x \), but on the stream of TDU welfare \( 1w = (w_1, w_2, \ldots) \). The interpretation is that each
generation exhibits a simple recursive form of \textit{nonpaternalistic} altruism (Ray, 1987), where the welfare of each generation $t$ is an additively separable function of its own wellbeing and the welfare of the next generation $t + 1$:

$$w_t = (1 - \rho)u(x_t) + \rho w_{t+1}.$$ 

Thus, the welfare of each generation $t$, $w_t$, equals $w_T^\rho(t|x)$. 

Along the increasing stream $1x$, infimum of TDU welfare over all generations equals $w_T^\rho(1x)$, the welfare of generation 1. However, $1x$ uniquely maximizes $w_T^\rho(1x)$ if the $u$-function is parameterized by $\eta_T$. It is therefore a trivial observation that $1x$ is the unique Calvo optimum with $\rho$ satisfying $1/A^* < \rho < 1$ and $\eta_T$ being given by (6).

The \textit{Chichilnisky criterion} evaluates streams according to a convex combination of TDU welfare and the limit of transformed wellbeing as time goes to infinity. It might be interpreted as a convex combination of TDU and the long-term average criterion, thereby avoiding dictatorship of both the present and the future. It follows that $1x$ is the unique Chichilnisky optimum with $\rho$ satisfying $1/A^* < \rho < 1$ and $\eta_T$ being given by (6), since then $1x$ is a TDU optimum and $\lim_{t \to \infty} x_t = \infty$.

The results of the present section can be summarized as follow:

**Proposition 1** Let $1x$ denote the wellbeing stream selected by the sustainable growth criterion in the AK model, when the gross productivity parameter equals $A^*$, and the growth rate in program (1) equals $g^*$, where $0 < g^* < A^* - 1$. It is taken as a datum that $g = g^*$ when $A = A^*$ appeals to ethical intuitions. The UU, TDU, SDU, RDU, Calvo and Chichilnisky criteria can be calibrated so that they all uniquely select $1x$ as the optimal wellbeing stream.

4 **Varying the rate of productivity**

In the present section I investigate how the different criteria behave when the gross productivity parameter $A$ of the AK is varied and takes on values that differ from $A^*$, but where I stick to the calibrations obtained in Section 3. These criteria are, in addition to the sustainable growth criterion with growth rate $g^*$: UU, TDU, SDU, RDU, the Calvo criterion, and the Chichilnisky criterion.

In the sustainable growth criterion where a wellbeing stream is selected to solve the $g^*$-SUS program (1), a balanced growth path with $\Lambda > 0$ exists if and only if $A > 1 + g^*$. Furthermore, this solution is time consistent. Thus, sustainable growth
criterion is **effective** and **non-wasteful** under this condition, but not otherwise. There is a balanced growth path also if \( A = 1 + g^* \), but then the savings rate

\[
s_t = \frac{g^*}{A - 1} = 1 \quad \text{for all } t,
\]

meaning that wellbeing equals zero at any point in time. Clearly, this is wasteful. The sustainable growth criterion is not **flexible** since the growth rate does not respond to different technological environments. Although the sustainable growth criterion is **sustainable** by respecting the rights of future generations whenever the rate of gross productivity is sufficiently high for the criterion to be **effective** and **non-wasteful**, it does not solve the intergenerational conflict for low rates of gross productivity.

By substituting \( A \) for \( A^* \) and \( \eta_U \) for \( \eta \), the condition for competitiveness under \( UU \) is changed from (4) to:

\[
(1 + g)^{-\eta_U} = \frac{x_{t+1}^{-\eta_U}}{x_t^{-\eta_U}} = \frac{u'(x_{t+1})}{u'(x_t)} = \frac{p_{t+1}}{p_t} = \frac{1}{A}. \]

Solving for \( g \) yields:

\[
g_U = A^{\frac{1}{\eta_U}} - 1 = A^{\ln(1 + g^*)/\ln A^*} - 1. \]

This uniquely determines the efficient balanced growth path, \( 1x^U \), defined by \( x_t^U = \Lambda_U(1 + g_U)^{t-1} \) for all \( t \geq 1 \), where \( \Lambda_U = (A - 1 - g_U)k_0 \). Since \( A > 1 \) and \( 0 < \ln(1 + g^*) < \ln A^* \), it follows that \( 0 < g_U < A - 1 \). Hence, \( UU \) is **effective** and **non-wasteful** for all \( A > 1 \). Furthermore, it is **flexible** since the growth rate \( g_U \) responds to changes in \( A \), with a higher \( A \) leading to a higher \( g_U \). Finally, the \( UU \) criterion is **sustainable** for all \( A > 1 \) in the sense of respecting the rights of future generations.

By substituting \( A \) for \( A^* \) and \( \eta_T \) for \( \eta \), the condition for competitiveness under \( TDU \) is changed from (5) to:

\[
\rho(1 + g)^{-\eta_T} = \frac{\rho x_{t+1}^{-\eta_T}}{x_t^{-\eta_T}} = \frac{\rho u'(x_{t+1})}{u'(x_t)} = \frac{p_{t+1}}{p_t} = \frac{1}{A}. \]

Solving for \( g \) yields:

\[
g_T = (A\rho)^{\frac{1}{\eta_T}} - 1 = (A\rho)^{\ln(1 + g^*)/\ln A^*} - 1. \]

This uniquely determines the efficient balanced growth path, \( 1x^T \), defined by \( x_t^T = \Lambda_T(1 + g_T)^{t-1} \) for all \( t \geq 1 \), where \( \Lambda_T = (A - 1 - g_T)k_0 \). Since \( 0 < \ln(1 + g^*) < \ln A^* \), it follows that \( 0 < g_T < Ap - 1 < A - 1 \) if \( A > 1/\rho \), \( g_T = 0 \) if \( A = 1/\rho \) and \( g_T < 0 \) if \( A < 1/\rho \). Hence, \( TDU \) is **effective** and **non-wasteful** for all \( A > 1 \). Furthermore, it is **flexible** since the growth rate \( g_T \) responds to changes in \( A \), with a higher \( A \) leading to
a higher $g_T$. However, the TDU criterion is *sustainable* in the sense of respecting the rights of future generations only if $A \geq 1/\rho$, but not if $1 < A < 1/\rho$.

It now follows from the argument for SDU optimality in Section 3 that $1x^T$ is SDU optimal whenever the efficient balanced growth path is increasing (i.e., in the case where $A > 1/\rho$), because then the inequalities $w^S_\rho(1x^T) = w_p^T(1x^T) > w_p^T(1\tilde{x}) \geq w^S_\rho(1\tilde{x})$ hold for any feasible stream $1\tilde{x}$ not identical to $1x^T$. However, for $A \leq 1/\rho$, then it follows from Asheim and Mitra (2010, Proposition 3) that SDU optimality corresponds to the equalitarian stream $1x^e$, defined by $x^e_t = (A - 1)k_0$ for all $t \geq 1$, ensuring that capital is maintained at its original level ($k_t = k_0$ for all $t \geq 1$) and corresponding to a growth rate $g_S = 0$. Hence, SDU is effective and non-wasteful for all $A > 1$. Furthermore, it is flexible since the growth rate $g_S$ responds to changes in $A$ for $A > 1/\rho$, with a higher $A$ leading to a higher $g_S = g_T$, even though $g_S$ is constant and equal to 0 for all $A \leq 1/\rho$. Finally, the SDU criterion is sustainable in the sense of respecting the rights of future generations for all $A > 1$.

The same conclusions hold for the RDU and Calvo criteria. Again, the result for RDU optimality can be established by adapting Zuber and Asheim (2012, Proposition 10) to the AK model. The result for Calvo optimality can be established by adapting the proof of part (2) of Calvo (1978, Proposition 2) to the AK model. Hence, both the TDU and Calvo criteria are effective and non-wasteful for all $A > 1$, flexible in that the sense the growth rate responds to changes in $A$ if and only if $A > 1/\rho$, and sustainable in the sense of respecting the rights of future generations for all $A > 1$.

The TDU optimal stream $1x^T$ is also Chichilnisky optimal if $A > 1/\rho$. However, if $A \leq 1/\rho$, there does not exist a Chichilnisky optimal stream. The problem is that the TDU part of the Chichilnisky criterion is increased by following $1x^T$ for a longer period of time, before ensuring that $\lim_{t \to \infty} x_t = \infty$ to “maximize” the second limiting part of the Chichilnisky criterion. However, if $1x^T$ is followed forever, then $\lim_{t \to \infty} x_t = (A - 1)k_0$ for $A = 1/\rho$ and $\lim_{t \to \infty} x_t = 0$ for $A < 1/\rho$. Hence, the Chichilnisky criterion behaves like TDU for $A > 1/\rho$, while not being effective otherwise.

The results of the present section can be summarized as follow:

---

5Conditions (2) and (3) of Asheim and Mitra (2010, Proposition 3) are satisfied since $p_t/p_{t-1} = 1/A \geq \rho$ for all $t \geq 1$, writing $p_0 = 1$, and $\sum_{t=1}^{\infty} p_t x_t^e = k_0 = \sum_{t=1}^{\infty} p_t \tilde{x}_t + p_t \tilde{k}_t \geq \sum_{t=1}^{\infty} p_t \tilde{x}_t$ for any feasible stream $1\tilde{x}$ and for all $\tau \geq 1$.

6Zuber and Asheim (2012, Proposition 10) is based on Asheim (1991, Proposition 6), where the proof of Case 2 must be adapted to the AK model to show that $1x^e$ maximizes $w_p^T(1x^e)$ over all non-decreasing streams $1x^+$ when $A \leq 1/\rho$. 

14
Proposition 2 Consider the sustainable growth criterion as well as the UU, TDU, SDU, RDU, Calvo and Chichilnisky criteria with the calibrations from Section 3. Allow the gross productivity parameter $A$ of the $AK$ to be varied, taking on values that differ from $A^*$. Only the UU, SDU, RDU and Calvo criteria satisfy all four desirable properties in the $AK$ model when the gross productivity parameter $A$ is varied, by being effective, non-wasteful, flexible and sustainable.

5 The Ramsey technology

Assume that the technology is given by an increasing, strictly concave, and twice continuously differentiable production function $f : \mathbb{R}_+ \to \mathbb{R}_+$, satisfying $f(0) = 0$ and $\lim_{k \to \infty} f'(k) = 0$. A wellbeing stream $x = (x_1, x_2, \ldots) \geq 0$ is feasible given an initial capital stock $k_0 > 0$ if there exists a capital stream $k = (k_1, k_2, \ldots) \geq 0$ such that

$$x_t + k_t - k_{t-1} = f(k_{t-1})$$

for all $t \geq 1$. Hence, in each period, net product $f(k_{t-1})$ is split between wellbeing $x_t$ and net investment $k_t - k_{t-1}$. This is the Ramsey technology, which is the standard technological environment for the analysis of economic growth.

With the assumption that the net marginal productivity of capital, $f'(k)$, approaches 0 as $k \to \infty$, it follows that the ratio of net product to capital, $f(k)/k$, approaches 0 as $k \to \infty$. The implication is that no stream with positive wellbeing growing at a constant positive rate $g$ is feasible. This leads to the conclusion that the sustainable growth criterion of selecting a wellbeing stream that solves the $g^*$-SUS program (1) selects no stream in the Ramsey technology with this assumption on the net marginal productivity of capital. Hence, the sustainable growth criterion is not effective in the Ramsey technology.

Also the UU criterion need not be effective in the Ramsey technology, even with the requirement that $\eta_U$ be greater than 1. A closed-form demonstration of this fact is most easily done in the continuous time version of the Ramsey technology: A non-negative wellbeing stream $(x(t))_{t=0}^{\infty}$ is feasible given an initial capital stock $k(0) > 0$ if there exists a non-negative capital stream $(k(t))_{t=0}^{\infty}$ such that

$$x(t) + \dot{k}(t) = f(k(t))$$

Asheim and Mitra (2010, Lemma 1) is a formal demonstration of this result, as $\sum_{t=1}^{\tau} \rho^{t-1} \Lambda (1+g)^{t-1}$ would diverge for any $\rho$ satisfying $1/(1+g) \leq \rho < 1$ if a wellbeing stream defined by $x_t = \Lambda (1+g)^{t-1}$ for all $t$ were feasible with $\Lambda > 0$ and $g > 0$.
for all \( t \geq 0 \). By giving the production function a iso-elastic form: \( f(k) = k^\alpha \), where \( 0 < \alpha < 1 \), the assumptions on \( f \) are fulfilled and a closed-form solution can be given. Note that the net marginal productivity of capital \( f'(k) \) then equals \( \alpha k^{\alpha - 1} \), so that the Keynes-Ramsey rule becomes:

\[
\alpha k(t)^{\alpha - 1} = \frac{\dot{x}(t)}{x(t)} \tag{8}
\]

Combining the Keynes-Ramsey rule (8) with

\[
\lim_{\tau \to \infty} e^{-\int_0^\tau \alpha k(t)^{\alpha - 1} dt} k(\tau) = 0 \tag{9}
\]

as a transversality condition is sufficient and necessary for UU optimality. The technological relation (7), where \( f(k) = k^\alpha \), together with the Keynes-Ramsey rule (8) imply that the savings rate \( s(t) \) defined by \( \dot{k}(t) = s(t)f(k(t)) \) is constant and equal to \( 1/\eta_U \).\(^8\) Substituting \( 1/\eta_U \) for \( s(t) \) and \( k(t)^\alpha \) for \( f(k(t)) \) in \( \dot{k}(t) = s(t)f(k(t)) \) and integrating yields:

\[
k(\tau) = e^{\int_0^\tau \frac{1}{\eta_U} k(t)^{\alpha - 1} dt} k(0)
\]

Hence, for the transversality condition (9) to hold, it must be that \( \alpha > 1/\eta_U \).

Hence, the UU criterion is effective if and only \( \eta_U > 1/\alpha > 1 \), implying that \( \eta_U > 1 \) is not sufficient for an UU optimum to exist. In this case, with \( \eta_U > 1/\alpha \), the UU criterion is non-wasteful for all \( k(0) > 0 \), flexible in the sense that the growth rate responds to changes in \( k(0) \), with a higher \( k(0) \) leading to a lower growth rate due to lower net marginal productivity of capital. Finally, the UU criterion is sustainable for all \( k(0) > 0 \) in the sense of respecting the rights of future generations.

However, if \( \eta_U \leq 1/\alpha \), then there exists no UU optimum. The problem is that short-run optimality, as dictated by the Keynes-Ramsey rule, leads to over-accumulation of capital. Hence, a given elasticity of marginal generalized utility \( \eta_U > 1 \) – as an expression of inequality aversion in social evaluation – fails to deliver a UU optimal stream in all the technological environments that satisfy the assumptions of the Ramsey technology. If \( f(k) \) is interpreted as a reduced form constant-returns-to-scale production function of capital and labor, with the labor force constant and normalized to 1, then a sufficiently high functional share of capital \( \alpha \) is needed for the UU criterion to be effective in the sense of being able to select an optimal stream.

Return now to the Ramsey technology in discrete time. For analyzing the properties of the remaining criteria in this technological environment, we need to define the

\(^8\)Use (7) combined with \( f(k) = k^\alpha \) and \( \dot{k} = sf(k) \) to obtain \( \dot{x}/x = s\alpha k^{\alpha - 1} \) and insert in (8).
modified golden rule. Define $k_\infty : (0, 1) \to \mathbb{R}_+$ by, for all $\rho \in (0, 1),$

$$k_\infty(\rho) = \min\{k \geq 0 : \rho(1 + f'(k)) \leq 1\}.$$ 

It follows from the properties of $f$ that $k_\infty$ is well-defined and continuous, and it is 
strictly increasing for all $\rho$ for which there exists $k \geq 0$ such that $\rho(1 + f'(k)) = 1$. For 
given $\rho \in (0, 1)$, $k_\infty(\rho)$ is the capital stock corresponding to the modified golden rule.

Beals and Koopmans (1969) show that there is a unique TDU optimal capital stream 
$1k^T$, with associated TDU optimal wellbeing stream $1x^T$, for given initial capital stock $k_0$. Furthermore, $1k^T$ and $1x^T$ are monotone, converging to $k_\infty(\rho)$ and $f(k_\infty(\rho))$, 
respectively. In particular, wellbeing is increasing if $k_0 < k_\infty(\rho)$, constant (and equal 
to $f(k_\infty(\rho))$) if $k_0 = k_\infty(\rho)$ and decreasing if $k_0 > k_\infty(\rho)$. Hence, TDU is effective and 
non-wasteful for all $k_0 > 0$. Furthermore, it is flexible in the sense that the growth rate responds to changes in $k_0$; in particular, increasing $k_0$ from below to above $k_\infty(\rho)$ 
changes positive growth in wellbeing to negative growth in wellbeing due to lower net 
marginal productivity of capital. However, the TDU criterion is sustainable in the sense 
of respecting the rights of future generations only if $k_0 \leq k_\infty(\rho)$, but not if $k_0 > k_\infty(\rho)$.

As in the case of the AK model, the TDU optimal stream is SDU optimal whenever 
the TDU optimal stream is increasing (i.e., the case where $k_0 < k_\infty(\rho)$). However, for 
$k_0 \geq k_\infty(\rho)$, then it follows directly from Asheim and Mitra (2010, Theorem 2) that 
SDU optimality corresponds to the equalitarian stream $1x^e$, defined by $x_t^e = f(k_0)$ for 
all $t \geq 1$, ensuring that capital is maintained at its original level ($k_t = k_0$ for all $t \geq 1$). 
Hence, SDU is effective and non-wasteful for all $k_0 > 0$. Furthermore, it is flexible in 
the sense that the growth rate responds to changes in $k_0$; in particular, increasing $k_0$ from below to above $k_\infty(\rho)$ changes a stream with increasing wellbeing to a stream of 
constant wellbeing due to lower net marginal productivity of capital. Finally, the SDU 
criterion is sustainable in the sense of respecting the rights of future generations for all 
$k_0 > 0$.

The same conclusions hold for the RDU and Calvo criteria. The result for RDU optimality follows directly from Zuher and Asheim (2012, Proposition 10), while the 
result for Calvo optimality follows directly from Calvo (1978, Proposition 2). Hence, 
both RDU and the Calvo criterion are also effective for all $k_0 > 0$. Furthermore, they 
are both non-wasteful, flexible in the sense that the growth rate responds to changes 
in $k_0$, and sustainable in the sense of respecting the rights of future generations for all 
k_0 > 0.

There is no Chichilnisky optimum in the Ramsey technology (see e.g. Asheim and
Ekeland, 2016, Proposition 3). As for the AK model, the existence problem arises since, by the Chichilnisky criterion, it is socially valuable to extend the period of time for which the TDU optimal stream is followed, while it is not optimal to follow the TDU optimal stream forever. However, in addition to not yielding an optimum, the Chichilnisky criterion is also time inconsistent. Therefore, in Asheim and Ekeland (2016), we investigate stationary Markov equilibria in the game that generations with Chichilnisky preferences play in the continuous time version of the Ramsey technology. We argue for plausibility of a particular equilibrium where behavior

- corresponds to the TDU optimum if the TDU optimum is increasing; in continuous time version this corresponds to small $k_0$ satisfying $f'(k_0) > \delta$ where $\delta$ is the continuous time discount rate;

- corresponds to the SDU/RDU/Calvo optimum, yielding a constant stream, for intermediate values of $k_0$ satisfying $\delta \geq f'(k_0) \geq (1 - \gamma)\delta$, where $(1 - \gamma)$ is the weight on the TDU part of the Chichilnisky criterion;

- is unsustainable, leading to a decreasing stream, for large values of $k_0$ satisfying $f'(k_0) < (1 - \gamma)\delta$.

Hence, in this equilibrium, the Chichilnisky criterion is effective and non-wasteful for all $k_0 > 0$. Furthermore, it is flexible in the sense that the growth rate responds to changes in $k_0$, so that the selected wellbeing stream is increasing for small values of $k_0$, constant for intermediate values of $k_0$, and decreasing for large values of $k_0$. However, in this equilibrium, the Chichilnisky criterion is sustainable in the sense of respecting the rights of future generations only for small and intermediate values of $k_0$, but not for large values of $k_0$.

The results of the present section can be summarized as follow:

**Proposition 3** Consider the sustainable growth criterion as well as the UU, TDU, SDU, RDU, Calvo and Chichilnisky criteria with the calibrations from Section 3. Only the SDU, RDU and Calvo criteria satisfy all four desirable properties in the Ramsey technology when the initial capital stock $k_0 > 0$ is varied, by being effective, non-wasteful, flexible and sustainable.

Note in particular that the UU criterion, which passed this test in the AK model, need not be effective in the Ramsey technology if the functional share of capital is too small.
Dasgupta and Heal (1974, 1979), Solow (1974) and Stiglitz (1974) developed the standard technological environment for the analysis of economic growth when natural resources are important. In their model, net production depends on reproducible capital $k_t^m$, the extraction $d_t$ of a natural exhaustible resource $k_t^n$, and the labor supply $\ell_t$. The natural resource is depleted by the resource use, so that $k_{t+1}^n = k_t^n - d_t$. The production function $\hat{f}(k_t^m, d_t, \ell_t)$ is concave, non-decreasing, homogeneous of degree one, and twice continuously differentiable. It satisfies $(\hat{f}_k(k^m_t, d_t, 1), \hat{f}_d(k^m_t, d_t, 1), \hat{f}_\ell(k^m_t, d_t, 1)) \gg 0$ for all $(k^m_t, d_t) \gg 0$ and $\hat{f}(k^m_t, 0, \ell_t) = \hat{f}(0, d_t, \ell_t) = 0$ (both reproducible capital and the natural resource are essential in the production). Moreover, given $(\tilde{k}_d^m, \tilde{d}) \gg 0$, there exists a scalar $\tilde{\chi}$ such that $(d\hat{f}_d(k^m_t, d_t, 1))/(\hat{f}_\ell(k^m_t, d_t, 1)) \geq \tilde{\chi}$ for $(k^m_t, d_t)$ satisfying $k^m_t \geq \tilde{k}_m$ and $0 \leq d \leq \tilde{d}$ (the ratio of the share of the resource to the share of labor is bounded away from zero when labor is fixed at unit level).

Assume, as before, that the labor force is constant and normalized to 1. Write $f(k^m_t, d_t) := \hat{f}(k^m_t, d_t, 1)$. Also assume that $f$ is strictly concave and that the cross partial derivative satisfies $f_{k^m_t, d}(k^m_t, d) \geq 0$ for all $(k^m_t, d) \gg 0$. A wellbeing stream $x^r = (x_1, x_2, \ldots) \geq 0$ is feasible given initial stocks $(k_0^m, k_0^n) \gg 0$ if there exist streams of capital, $1k^m = (k_1^m, k_2^m, \ldots) \geq 0$, and resource, $1k^n = (k_1^n, k_2^n, \ldots) \geq 0$, such that

$x_t + k_t^m - k_{t-1}^m = f(k_{t-1}^m, k_{t-1}^n - k_t^n)$

for all $t \geq 1$. Hence, net production $f(k_{t-1}^m, k_{t-1}^n - k_t^n)$ is split between wellbeing $x_t$ and net investment $k_t^m - k_{t-1}^m$ in reproducible capital at each time $t$.

The assumptions made so far do not ensure that it is feasible to maintain a constant and positive wellbeing level forever. Therefore, assume in addition that there exists from any $(k_0^m, k_0^n) \gg 0$ a constant stream with positive wellbeing. Cass and Mitra (1991) give a necessary and sufficient condition on $f$ for this assumption to hold.\textsuperscript{9} Under this additional assumption there exists an efficient constant wellbeing stream from any $(k_1^m, k_1^n) \gg 0$ (see Dasgupta and Mitra, 1983, Proposition 5). A technology satisfying the above assumptions is referred to as a Dasgupta-Heal-Solow-Stiglitz (DHSS) technology.

Even though a stream with constant and positive wellbeing is feasible, no stream with positive wellbeing growing at a constant positive rate $g$ is feasible.\textsuperscript{10}

\textsuperscript{9}Mitra et al. (2013) do likewise in the continuous time version of the model.

\textsuperscript{10}Asheim and Mitra (2010, Lemma 2) is a formal demonstration of this result, as $\sum_{t=0}^{\tau} \rho^{t-1} \Lambda(1+g)^{t-1}$.
to the conclusion that the sustainable growth criterion of selecting a wellbeing stream that solves the $g^s$-SUS program (1) selects no stream in the DHSS technology with the assumptions above. Hence, as for the Ramsey technology, the sustainable growth criterion is not effective in the DHSS technology.

Also the UU criterion need not be effective in the DHSS technology. A closed-form demonstration of this fact is most easily done in the continuous time version of the DHSS technology: A non-negative wellbeing stream $(x(t))_{t=0}^{\infty}$ is feasible given an initial stock $(k^m(0), k^n(0)) \gg 0$ if there exists non-negative streams of capital $(k^m(t))_{t=0}^{\infty}$ and resource $(k^n(t))_{t=0}^{\infty}$ such that

$$x(t) + \dot{k}^m(t) = f(k^m(t), -\dot{k}^n(t))$$

for all $t \geq 0$. By giving the production function a Cobb-Douglas form: $f(k^m, -\dot{k}^n) = (k^m)^\alpha (-\dot{k}^n)^\beta$, where $0 < \beta < \alpha < 1$ and $\alpha + \beta < 1$, the assumptions on $f$ are fulfilled and a closed-form solution can be given, as demonstrated by Asheim et al. (2007). Furthermore, it follows from Asheim et al. (2007, Theorem 10 and 12) (see also Dasgupta and Heal, 1979, pp. 303–308) that a UU optimum exists if and only if

$$\alpha - \beta > \frac{1 - \beta}{\eta_U}.$$ 

Hence, the UU criterion is effective if and only $\eta_U > (1 - \beta)/(\alpha - \beta) > 1$, implying that $\eta_U > 1$ is not sufficient for an UU optimum to exist in the DHSS technology, echoing the similar result in the Ramsey technology. A sufficiently large functional share of capital $\alpha$ and a sufficiently small functional share of resource input $\beta$ is needed for an UU optimum to exist. With $\eta_U > (1 - \beta)/(\alpha - \beta)$, the UU criterion is non-wasteful and sustainable in the sense of respecting the rights of future generations for all $(k^m(0), k^n(0)) \gg 0$, and flexible in the sense that the growth rate responds to changes in $(k^m(0), k^n(0))$. However, no UU optimum exists with $\eta_U \leq (1 - \beta)/(\alpha - \beta)$.

Already Dasgupta and Heal (1974) demonstrated in the continuous time version of the DHSS model that wellbeing is forced towards 0 as time goes to infinity under the TDU criterion for any positive discount rate $\delta$ and specification of the $u$-function that turns wellbeing into generalized utility. The same conclusion holds in the discrete time version for any discount factor $\rho$ between 0 and 1. The reason is that the net productivity of capital is forced towards zero in any stream where wellbeing is bounded

would diverge for any $\rho$ satisfying $1/(1 + g) \leq \rho < 1$ if a wellbeing stream defined by $x_t = \Lambda(1 + g)^{t-1}$ for all $t$ were feasible with $\Lambda > 0$ and $g > 0$. 

20
away from zero. So, even though the TDU criterion is effective and non-wasteful for all initial stocks \((k_0^m, k_0^n) \gg 0\), it is never sustainable in the sense of respecting the rights of future generations.

In contrast, the SDU, RDU and Calvo criteria give always rise to a sustainable wellbeing stream, for any \((k_0^m, k_0^n) \gg 0\). This wellbeing stream has the property of maximizing the TDU criterion over all non-decreasing wellbeing streams. Since the TDU optimum is not non-decreasing, the stream selected by the SDU, RDU, and Calvo criteria differs from the stream selected under TDU. To describe this wellbeing stream, denote by \(x^e(k_0^m, k_0^n)\) the positive and constant level of wellbeing that can be sustained forever along an efficient constant consumption stream from \((k_0^m, k_0^n) \gg 0\).

It is possible to attach a sequence of shadow prices \(\left(p_1(k_0^m, k_0^n), p_2(k_0^m, k_0^n), \ldots, p_t(k_0^m, k_0^n), \ldots\right)\) to the corresponding stationary consumption stream (for a characterization of the prices, see Asheim and Mitra, 2010, Lemma 3). Write

\[
\rho_\infty(k_0^m, k_0^n) = \frac{\sum_{t=1}^{\infty} p_t(k_0^m, k_0^n)}{\sum_{t=0}^{\infty} p_t(k_0^m, k_0^n)},
\]

where \(p_0(k_0^m, k_0^n) = 1\), for the long-run discount factor at time 0 supporting this stationary stream.

The unique SDU optimal wellbeing stream \(x^S\) is characterized as follows:

(a) If \(\rho_\infty(k_0^m, k_0^n) < \rho\), then \(x^S\) is the non-decreasing stream maximizing TDU welfare over all feasible and non-decreasing streams. This stream has the property that there exists \(\tau = \min\{t \geq 0 : \rho_\infty((k_t^m)^S, (k_t^n)^S) \geq \rho\}\) such that

\[
x_t^S < x_{t+1}^S \text{ for } t \leq \tau,
\]

\[
x_t^S = x^e((k_\tau^m)^S, (k_\tau^n)^S) \text{ for all } t > \tau.
\]

(b) If \(\rho_\infty(k_0^m, k_0^n) \geq \rho\), then \(x^S\) is the egalitarian stream with \(x_t^S = x^e(k_0^m, k_0^n)\) for all \(t \geq 1\).

The result that \(x^S\) is the unique SDU optimal wellbeing stream follows directly from Asheim and Mitra (2010, Theorem 3). The result that \(x^S\) is also the unique RDU optimal wellbeing stream follows directly from Zuber and Asheim (2012, Proposition 11). The analysis with the Calvo criterion is more complicated, as an optimal time consistent stream does not exist in case (a) (see Asheim, 1988, Theorem 1). However,
is the unique equilibrium of the intergenerational game, under the assumption that the optimal stream is followed as soon as one exists (see Asheim, 1988, Theorem 2). To see that stream is not optimal in case (a), but an equilibrium, observe that generation \( \tau + 1 \) would want the generation \( \tau + 2 \) to enjoy wellbeing on its behalf as \( \rho \) times the gross marginal instantaneous productivity of capital exceeds 1. However, if generation \( \tau + 1 \) makes such a sacrifice, generation \( \tau + 2 \) would want to share this wellbeing with its descendants. However, if generation \( \tau + 2 \) does so, then it is better for generation \( \tau + 1 \) to stick to \( x^S \) since the gross marginal productivity of capital is decreasing along \( x^S \).

Therefore, the SDU, RDU and Calvo criteria are effective in the DHSS technology—in the sense of selecting a time consistent stream—for all \( (k^m_0, k^n_0, k^m_0, k^n_0) \gg 0 \). They are also non-wasteful, flexible in the sense that the growth rate responds to changes in \( (k^m_0, k^n_0) \), and sustainable in the sense of respecting the rights of future generations for all \( (k^m_0, k^n_0) \gg 0 \).

As for the Ramsey technology, there is no Chichilnisky optimum in the DHSS technology. There is yet no game theoretic analysis of the Chichilnisky criterion in the DHSS technology, not even in the continuous time version of the model, so it is premature to speculate on the properties of such a Chichilnisky equilibrium in this technological environment.

The results of the present section can be summarized as follow:

**Proposition 4** Consider the sustainable growth criterion as well as the UU, TDU, SDU, RDU, Calvo and Chichilnisky criteria with the calibrations from Section 3. Only the SDU, RDU and Calvo criteria satisfy all four desirable properties in the DHSS technology when the initial stocks \( (k^m_0, k^n_0) \gg 0 \) are varied, by being effective, non-wasteful, flexible and sustainable.

7 Discussion

In this paper I have evaluated different criteria of intergenerational equity by mapping the consequences of the criteria in various technological environments, and observed to which extent they yield social choice mappings that are effective (in the sense of selecting a time consistent stream), non-wasteful (in the sense that the selected stream is efficient), flexible (in the sense that the growth rate of the selected stream responds to changes in the technological environment), and sustainable (in the sense that the selected stream respect the rights of future generations by not rendering them worse
off than the present generation). The different criteria were calibrated so that they give rise to the same efficient balanced growth path in the AK model for a given value $A^*$ of the gross productivity parameter $A$, before being subjected to the technological environments that arise when varying $A$ in the AK model, as well as to the Ramsey and DHSS technologies. The results are summarized in Table 1.

[Table 1 about here.]

Being effective and non-wasteful are basic and undisputable properties. Flexibility seems necessary for ensuring that a criterion is effective, as is illustrated in Table 1 by the results on the sustainable growth criterion of selecting a wellbeing stream that solves the $g^*$-SUS program (1). Lastly, sustainability is the position that Roemer (2011, 2013) argues for in the quotes of the introduction; this is a position that I support.

The table shows that the UU criterion is not a viable alternative, as it need not be effective in the Ramsey and DHSS technologies. The criterion that economists usually endorse, TDU, does fine in the AK model and in the Ramsey technology as long as the economy is sufficiently productive. Hence, the endorsement of TDU might from a pragmatic perspective be based on a view that these are the “relevant” technological environments and on the fact that it is not to the disadvantage of future generations in these settings that they are discriminated against by TDU. However, if productivity is low, or if natural resources are important (as they are in the DHSS technology), then the TDU criterion does not yield sustainable outcomes.

The Chichilnisky criterion is not effective, at least not unless a game theoretic analysis is invoked in response to the time inconsistency of this criterion. And even in the game that generations with Chichilnisky preferences play in the continuous time version of the Ramsey technology, the plausible equilibrium does not lead to a sustainable outcome if productivity is low.

Table 1 shows that the remaining criteria, SDU, RDU, and the Calvo criterion, do well with respect to all the four desirable properties in all the considered technological environments. In these criteria, discounting of generalized utility is not allowed to be to the disadvantage of future generations, at least not in technological environments (like the ones I consider) with positive net marginal productivity of capital.

The Calvo criterion is of particular interest, as it combines the extreme egalitarianism of the maximin principle—which is endorsed by John Roemer—with altruism for future generations. In fact, Calvo’s (1978) contribution arose as a response to Rawls’s (1999) discussion of intergenerational equity, as interpreted by Arrow (1974)
and Dasgupta (1974). It shows how sustainable growth can be combined with the maximin principle, because generations with altruism choose to let their descendants enjoy wellbeing on their behalf.

Also the SDU criterion has a motivation that is close to that conveyed by Roemer (2011, 2013) in the quotes of the introduction. It captures the intuition that we have an obligation to assist future generations if they are worse off than us, but we may choose to give them the means for achieving a higher wellbeing than the one enjoyed by ourselves.

The RDU has a different motivation, as generations are treated completely symmetric, with rank-discounting being an expression of social aversion to inequality. In particular, with negative net marginal productivity of capital between two periods, RDU would allow a generation a wellbeing level that exceeds the wellbeing that some future generation will enjoy. However, in the technological environments that I have considered in this paper, RDU yields the same outcome as the SDU and Calvo criteria.

From a technical point of view, the discount factor $\rho$ between 0 and 1 that enters into the SDU, RDU and Calvo criteria has the property of ensuring that the criteria are effective. When $\rho$ approaches 1, the outcome approaches the UU optimum when this exists. For $\rho$ sufficiently small, the outcome is an egalitarian wellbeing stream, hence, the outcome that would have arisen if the maximin criterion had been applied.

As for the choice of the growth rate $g^*$ in the $g^*$-SUS problem when applied to the $AK$ model, the parameters of the SDU, RDU and Calvo criteria, the discount factor $\rho$ and the parameter of inequality aversion $\eta$, must be chosen according to ethical intuitions—or perhaps, in line with the quotes of the introduction, how we believe that generations will choose to make sacrifices for their descendants. Even for a given choice of the growth rate $g^*$ in the $AK$ model with with the gross productivity parameter $A$ equal to a particular value $A^*$, there is trade-off between $\rho$ and $\eta$ as shown by eq. (6): More discounting (in the form of a lower discount factor $\rho$) corresponds to less inequality aversion (in the form a lower parameter of inequality aversion $\eta$) and less responsiveness to changes in productivity.\footnote{The two parameters can be calibrated independently if there are two different combinations of gross productivity and growth rate, $(A^*, g^*)$ and $(A^{**}, g^{**})$, that appeal to ethical intuitions in the $AK$ model.}

Throughout this paper I have abstracted from exogenous or endogenous variation of population size. In particular, population has been assumed to be constant and normalized to 1, implying that the analysis has abstracted from intragenerational inequality. Moreover, I have assumed zero probability of extinction, and that generations
succeed each other without overlapping in a deterministic setting. This setting has allowed a focus on the ethics of intergenerational distribution.

As Stéphane Zuber and I show in Asheim and Zuber (2014, 2016), the RDU can be generalized to settings with variable population and intergenerational risk. I do the same for SDU in Dietz and Asheim (2011). Practical use of the Calvo criterion requires that such issues be resolved also for this criterion of intergenerational equity. The properties of these criteria may well differ when expanding the domain of technological environments by considering also population issues and intergenerational risk.
