

THE CONSERVATION MULTIPLIER

Bård Harstad

October 16, 2020

Abstract

Every government that controls an exhaustible resource must decide whether to exploit it or to conserve and thereby let the subsequent government decide whether to exploit or conserve. This paper develops a positive theory of this situation and shows when a small change in parameter values has a multiplier effect on exploitation. The multiplier is taken advantage of by a lobby paying for exploitation; it can also be taken advantage of by a donor compensating for conservation, but there is a fundamental asymmetry between the two. A normative analysis uncovers when compensations are optimally offered to the president, the party in power, the general public, or to the lobby group.

Keywords: dynamic games, exhaustible resources, deforestation, political economy, lobbying, multiple principals, conservation

1. INTRODUCTION

This paper presents a tractable dynamic game of resource exploitation between consecutive governments. The model is employed to illustrate how the game can be taken advantage of by a principal who prefers exploitation, or by a principal who prefers conservation, and how the two interact.

The model can be applied to several situations, and it is consistent with recent deforestation in the tropics. The deforestation rate in the Brazilian Amazon is influenced by many factors but, most of all, it is in the hands of the government. Burgess et al. (2019:3) analyze satellite data and find that they "*demonstrate the remarkable reach of the Brazilian state to exploit or conserve its natural resources.*"¹ The current government has abolished conservation policies and effectively encouraged illegal deforestation. As a consequence, the rate was 30 percent higher in December, 2019, relative to a year earlier, and it is, so far, 25 percent higher in 2020 than in 2019.²

The stakes are enormously high in the Amazon. Agricultural sectors benefit when the land is cleared, but the world community, and supporters of globally stringent climate change policies, lose. Franklin and Pindyck (2018) estimate that the average marginal social cost of deforestation in the Brazilian Amazon increases from \$9,000 to \$35,000 per hectare when deforestation rates return to the high levels of the early 2000s. (See also Strand et al., 2018). The estimates vastly exceed the cost of conservation (Stern, 2008; Busch et al., 2012; Edenhofer et al., 2014).

Stakeholders are thus willing to pay to influence the decisions. On one side, because deforested land allows for farming and cattle raising, the agricultural sector has for decades supported, and lobbied for, a policy that permits extensive deforestation.³ On the other side, developed countries are increasingly offering payments in return for con-

¹In particular, the high deforestation rates in the early 2000s were "*associated with Brazilian policies to develop the Amazon,*" (p. 2) but "*this policy stance was sharply reversed in the 2006-2013 period with laws to protect the Amazon rainforest being introduced and enforced*" (p. 3). For the subsequent period, the authors find "*concrete evidence that the Brazilian state is now favoring exploitation over conservation*" (p. 2).

servation through the United Nation program Reduced Emission from Deforestation and forest Degradation (REDD+).⁴ Over time, these types of conflicts have become more significant in several countries because of technological improvements (both in logging machinery and satellite monitoring) that give governments more influence on whether the resource will be conserved or exploited. The stakes have increased in the agricultural sector thanks to new trade agreements that enlarge the markets. At the same time, the threat of climate change and the emergence of global climate policies imply that the world community has a greater willingness to pay for conservation than before.⁵

These developments raise positive and normative questions. When can high exploitation rates be the outcome of the game between governments? What are the roles of political stability, institutions, and of improved conservation technology and exploitation capacity? Are lobby groups taking advantage of the dynamic game between the governments, and why aren't they outcompeted by stakeholders paying for conservation? How should compensations for conservation be designed to be efficient?

The purpose of this paper is to provide a positive theory consistent with facts, so that we can also trust the normative implications. In every period, there is a president deciding on whether to exploit or conserve an exhaustible resource. If the president conserves the resource, the next-period president must decide whether to continue conserving. It is valuable to conserve as well as to exploit, and the value of exploitation is assumed to be larger when one is in power than when another party is in power.⁶ The game ends when the resource is (fully) exploited. The model permits resource extraction to be gradual or probabilistic.

Different presidents can have different preferences. With sufficient heterogeneity, the

⁴These payments are, in part, motivated by improvements in conservation technology (such as satellite monitoring and policing capacity). In the period 2005–2012, the Brazilian government took advantage of this technology, and the payments, and proved that deforestation can be reduced dramatically when there is a political will. Norway, the biggest contributor to the REDD+ program, paid Brazil \$1.2 billion in return. In 2019, however, the compensation schemes were halted, in part because of disagreements over whether the payments should be earmarked or instead be used at the discretion of the current government.

⁵Burgess et al. (2019) observe a development with "*better monitoring (through use of satellite data)*" (p. 13) and, simultaneously, a "*growing political power of the agriculture producers*" (p. 8).

⁶This is natural and, empirically, Caselli and Michaels (2013:230-231) find that "*some of the revenues from oil [in Brazil] disappear before turning into the real goods and services they are supposed to be used for*" and "*the evidence leads us to conclude that the missing money result is explained by a combination of patronage spending/rent sharing and embezzlement.*"

current president expects that the next president will exploit with some probability. If this probability is significant, the value of conserving today is limited and the probability for exploitation today becomes large, as well. This mechanism leads to unraveling, or a multiplier effect: With a small change in parameters the probability that the current president exploits can increase by a lot. The expected rate of extraction can thus be much larger than it would have been if the party were certain to stay in power forever.

Two "principals" can influence the presidents. A lobby group, benefiting from exploitation, pays favors to a president that exploits. When the president anticipates that future presidents are more likely to exploit because of the lobby, the president is more likely to exploit right away, even without (or with little) payments. If a donor provides compensations in return for conservation, the president becomes more likely to conserve. When the current president anticipates that the compensations will make conservation more likely also in the future, then conservation becomes more valuable today, and thus the president becomes willing to conserve for a lower price. Each principal benefits from the multiplier, but they are fundamentally asymmetric: the exploitation lobby only needs to pay the president one single time to succeed, whereas the stakeholder paying for conservation needs to pay in every period. The cost is thus higher for this stakeholder which, therefore, is less likely to succeed. Consequently, the presence of the principals makes exploitation more likely, even when the sum of their values make conservation efficient.

The positive theory is consistent with a number of empirical facts.⁷ This consistency suggests that we should also consider the normative implications that are policy relevant, e.g., regarding how compensation payments should be targeted. On the one hand, current payments may be most persuasive if the current president has full discretion regarding how the funds are to be spent. On the other hand, if the compensation benefits the general public, and not only the sitting president, then future conservation becomes directly valuable to the current president. Specified conditions describe when earmarking

⁷Bohn and Deacon (2000) found that political risk increases deforestation (but not necessarily investment-intensive resource extraction). Collier (2010:1124) wrote that: "*ministers in the transitional government in the Democratic Republic of Congo (DRC) knew that they only had around three years in office. During this period many contracts were signed with resource extraction companies conceding very generous terms in return for signature bonuses that cashed in the value of the natural assets to the society.*" The theory also predicts that the multiplier is larger when the president has a lot of discretion, as when there are few checks-and-balances. This is consistent with the empirical evidence of Collier and Hoeffler (2009), for example, who show that checks-and-balances mitigate the resource curse.

the funds can be more effective. I also describe when the donor benefits from paying the lobby group to not lobby. This strategy is feasible in practice if the donor cooperates with farmers and agricultural associations instead of with governments (Angelsen et al., 2018).

Literature.—Dynamic games between successive governments have been studied extensively. It is well known that political turnover leads to less investments in state capacity (Besley and Persson, 2009; 2010), more redistribution and depletion of capital (Tornell and Lane, 1999), less stabilization (Alesina and Drazen, 1991), and the accumulation of debt (Persson and Svensson, 1989; Alesina and Tabellini, 1990; Tabellini, 1991; Battaglini and Coate, 2008).

Similar results appear in resource economics. Extraction rates are shown to be larger if one fears nationalization (Long, 1975), if there are multiple dynasties (Nowak, 2006), or if the resource fuels conflicts (van der Ploeg and Rohner, 2012). More specifically, Robinson et al. (2006) show that an incumbent extracts more if he is unlikely to be reelected. Their two-period model is extended by Ryszka (2013) and van der Ploeg (2018), who further investigate how a higher probability of being removed from office leads to more rapacious depletion today.⁸

The model in this paper is especially tractable and it uncovers the multiplier. Given the insight in the above-mentioned literature, however, the primary contribution of this paper is to employ this tractable model to study how multiple principals take advantage of the dynamic game between the governments. The multiplier implies that the returns to lobbying can be high, and the asymmetry between paying once for expropriation vs. always for conservation leads to a fundamental inefficiency. This inefficiency contrasts the standard finding with menu auctions (Grossman and Helpman, 1994; Dixit et al., 1997), vote buying (Dekel et al., 2008), and even with informational lobbying (Battaglini, 2002), that when all stakeholders lobby, the outcome is efficient. The inefficiency is not emphasized in the dynamic lobbying models, either.⁹

⁸There is a theoretical literature on dynamic contribution games (see Bagnoli and Lipman, 1989; Marx and Matthews, 2000, Battaglini et al., 2014, and subsequent papers), but the present game is different since every player fears that later players will end the game (by exploiting the resource). In much of the contribution games literature, in contrast, each player fears that subsequent players will not contribute, i.e., that the game will continue for a long time.

⁹Levy and Razin (2013) study two principals influencing policy-making in a dynamic game, but they focus on voting (among legislators) and assume that the principals can influence the choice of

With this, I add a new political economy perspective to our understanding of deforestation and the design of compensations. Existing theories focus on contract-theoretic problems such as moral hazard (Gjertsen et al., 2016; Kerr, 2013), private information (Mason and Plantinga, 2013; Mason, 2015), observability (Delacote and Simonet, 2013), liquidity constraints (Jayachandran, 2013), and additionality (Jack and Jayachandran, 2019). Burgess et al. (2012) showed that deforestation increased in election years and after decentralization reforms in Indonesia (see Pailler, 2018, for a more recent study of Brazil), and Harstad and Mideksa (2017) provided a theoretical framework to explain these empirical findings and to investigate how conservation contracts should be designed when there are competing jurisdictions. These frameworks are static, however.¹⁰

Outline.—The next section presents the positive theory with rotation of political power and the multiplier effect and relates the predictions to evidence. Section 3 shows how the multiplier can be taken advantage of – not only by a lobby group paying for exploitation – but also by a donor paying for conservation. The normative analysis in Section 4 shows when the donor achieves cost-effective conservation by paying the party, the public, or the lobby group, instead of paying the president. Section 5 discusses time inconsistency and Markov strategies, and Section 6 concludes. The Appendix contains all proofs and an Online Appendix analyzes several extensions.

2. THE DYNAMICS OF CONSERVATION AND EXPLOITATION

2.1. *A Stopping Game*

Time is discrete and there is a infinite number of periods. Every period t is associated with exactly one player, the president P_t ("he").

Actions.— P_t decides only on $s_t \in [\underline{x}, \bar{x}] \subseteq [0, 1]$. Decision variable s_t can be interpreted as the probability of exploiting an exhaustible resource, such as a biodiverse

amendment, but not actual votes. Schopf and Voss (2017; 2019) analyze lobbying of a government extracting a resource, but the government (or planner) is long-lived. Neither the multiplier effect, nor the inefficiency in the present paper, arises in these papers.

¹⁰Harstad (2016) analyzed a dynamic game between a country who prefers to exploit, and a donor who may buy or lease a resource for conservation, but that game did not permit rotation of political power and thus, again, it failed to uncover the multiplier. Furthermore, Harstad (2016) relied on complete information and mixed-strategy equilibria and permitted neither lobbying nor alternative targets for the funding.

tropical forest. Alternatively, as I will explain in the next subsection, s_t can be interpreted as the fraction of the resource that is extracted at time t . When s_t is interpreted as a fraction, it is reasonable to assume that there are boundaries to how fast the resource can be exploited and to the extent to which it can be conserved. However, also when s_t is interpreted as a probability, it may be difficult for P_t to guarantee with certainty that the resource is, or is not, exploited. The amount of discretion, $\bar{x} - \underline{x}$, may also be limited by institutional checks-and-balances. For these reasons, I permit $\underline{x} > 0$ and $\bar{x} < 1$, but the reader is welcome to restrict attention to the simpler situation in which $\underline{x} = 0$ and $\bar{x} = 1$.

Payoffs.—There is a benefit from exploiting the resource. To allow for a conflict of interest, let $\bar{b} > 0$ be the benefit for the party in power, and $b \geq 0$ for everyone not in power. I assume that $\Delta \equiv \bar{b} - b > 0$, meaning that any P_t benefits more if he, or his party, exploits the resource, than if another party exploits the resource. This assumption is natural, since the ruler can spend (parts of) the revenues on perks (see Footnote 6). For this reason, it might be reasonable that Δ is correlated with the amount of corruption in the country. The Online Appendix explains how the results shed light on alternative applications in which $\Delta < 0$ can be natural.

There is also a cost associated with exploiting the resource or, equivalently, there is a benefit from conservation. The per-period payoff to P_t if the resource is conserved at time $\tau \geq t$ is $c_P > 0$. Thus, P_t 's payoff from conserving indefinitely is $c_P / (1 - \delta)$, where $\delta \in (0, 1)$ measures the common discount factor.

To allow future decisions to be uncertain, the subscript on c_P indicates that various individuals and presidents may value conservation differently. To model this uncertainty, let $c_P = \underline{c} + \theta_t \in [\underline{c}, \underline{c} + \sigma]$, where $\underline{c} > 0$ is a common component while θ_t characterizes the type of president in power at time t . Every θ_t is i.i.d. uniformly on $[0, \sigma]$.¹¹

Presidents and Parties.—The president P_t is long-lived but will not be a president in later periods. Thus, one learns nothing about future decisions from observing θ_t today.

¹¹The model and the results stay unchanged if the gain from extraction, b , instead of \underline{c} , were heterogeneous and uncertain in this way, and also if \underline{c} , instead of b , were dependent on whether one's own party makes the decision: The Appendix permits both b and c to depend on whether one's own party acts, and they can also be different for P_t when he is the president and when he is not. The Online Appendix explains that other types of uncertainties (regarding the resource price, for example), or convex extraction costs, lead to similar results.

Nevertheless, there may be some chance that P_t can enjoy \bar{b} , rather than b , if the resource is exploited in the future. To be specific, suppose P_t is associated with a political party and enjoys \bar{b} , rather than b , if and only if this party exploits the resource in the future. Let $p \in [0, 1]$ be the probability that the current president's party is out of office in any later period. Then, P_t enjoys \bar{b} if he extracts the resource, but expects $pb + (1 - p)\bar{b} \leq \bar{b}$ if the resource is exploited later. If there are n identical parties, then we may have $1 - p = 1/n$. The Online Appendix explains how the model can permit heterogeneous political parties and elections to endogenize p .

Timing.—The identity of P_t is determined in period t . Technically, this means that θ_t is drawn from $[0, \sigma]$. Thereafter, P_t decides on $s_t \in [\underline{x}, \bar{x}]$ and receives the expected payoff $s_t\bar{b} + (1 - s_t)(\underline{c} + \theta_t)$. Thus, with probability s_t , the game ends after period t . With probability $1 - s_t$, the game continues to period $t + 1$. Then, and in any future period, P_t 's party is out of office with probability p . This simply means that P_t benefits b rather than \bar{b} if the resource is exploited.

The First Best.—If the payoff of the ruling party is negligible relative to everyone else, it is optimal to increase exploitation (from \underline{x} to \bar{x}) if:

$$b > \frac{c}{1 - \delta}, \text{ where } c \equiv \underline{c} + \sigma/2. \quad (1)$$

Equilibrium Concept.—The game is stationary, every subgame is equivalent, and the history is "payoff irrelevant" as long as the resource has not been exhausted. Thus, I will look for an equilibrium in stationary strategies. (The Online Appendix considers other SPEs.) In fact, if later presidents can observe the outcome only, and not the chosen probability $s_t \in [\underline{x}, \bar{x}]$, then every subgame-perfect equilibrium (SPE) *must* be stationary. Hence, P_t 's strategy, $s_t(\theta_t)$, is a function of θ_t alone. Since the distribution of θ_t is independent of time, the probability that any *later* president exploits is constant. This stationary probability is referred to as $x \equiv E_{\theta_\tau, s_\tau}(\theta_\tau)$, $\tau > t$. If P_t conserves, his continuation value starting at any later period is:

$$V^P = pbx + (1 - p)\bar{b}x + (1 - x)(c_P + \delta V^P) = \frac{pbx + (1 - p)\bar{b}x + (1 - x)c_P}{1 - \delta(1 - x)}. \quad (2)$$

Anticipating V^P , P_t solves:

$$\arg \max_{s_t \in [\underline{x}, \bar{x}]} s_t \bar{b} + (1 - s_t) (c_P + \delta V^P). \quad (3)$$

2.2. Probabilistic vs. Gradual Extraction

As an alternative to interpreting s_t and x as probabilities of exploitation, they can be interpreted as the *fractions* that are extracted from an exhaustible resource stock this and later periods. That is, if the stock is S_t , then $S_{t+1} = (1 - s_t) S_t$, and $S_{\tau+1} = (1 - x) S_\tau$ for $\tau > t$. For this situation, suppose P_t 's payoff in any later period, $\tau > t$, is linear: $pbxS_\tau + (1 - p)\bar{b}xS_\tau + (1 - x)S_\tau c_P$, when xS_τ is extracted and $(1 - x)S_\tau$ is conserved.

Lemma 1. *The set of Markov-perfect s_t 's, when s_t represents a fraction, equals the set of subgame-perfect s_t 's, when s_t represents a probability.*

The Appendix verifies that all results hold with gradual extraction. The Online Appendix permits convex (non-linear) extraction costs.

With Lemma 1, \underline{x} and \bar{x} can be interpreted as the minimum and maximum fractions, respectively, that can be exploited in any given period. Although the model permits both interpretations, it is helpful to fix ideas and refer to s_t as the probability.¹²

2.3. Strategies

When P_t 's continuation value is given by (2), the solution to problem (3) is very simple. P_t 's equilibrium strategy, $s_t(\theta_t)$, is:

$$\begin{aligned} \underline{x} \text{ if } \theta_t > \theta(x), \quad [\underline{x}, \bar{x}] \text{ if } \theta_t = \theta(x), \text{ and } \bar{x} \text{ if } \theta_t < \theta(x), \text{ where} \\ \theta(x) \equiv \delta p \Delta x + (1 - \delta) \bar{b} - \underline{c}. \end{aligned} \quad (4)$$

The probability of exploitation, $x_t \equiv \mathbb{E}_{\theta_t} s_t(\theta_t)$, can be written as:

$$x_t = \underline{x} \Pr(\theta_t \geq \theta(x)) + \bar{x} \Pr(\theta_t < \theta(x)).$$

¹²The lemma rests on the assumption that when s_t measures a probability, later presidents can observe whether the resource is exploited, but not the choice of s_t . If the probability s_t were observable, the word *stationary* should be added before *subgame-perfect* in Lemma 1.

Given that θ_t is uniformly distributed on $[0, \sigma]$, we can easily see when the equilibrium level for x_t depends on the expected x in later periods:

$$x_t(x) = \left\{ \begin{array}{ll} \underline{x} & \text{if } \theta(x) \leq 0 \\ \underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \theta(x) & \text{if } \theta(x) \in [0, \sigma] \\ \bar{x} & \text{if } \theta(x) \geq \sigma \end{array} \right\}. \quad (5)$$

Proposition 1.

- (i) If $p\Delta = 0$, exploitation at t is independent of expected future exploitation: $x_t = x_t(0)$.
- (ii) If $p\Delta > 0$, exploitation at t increases with expected future exploitation: $\partial x_t / \partial x > 0$.

Part (i) of the proposition shows that, just as in the first best, x_t is independent of the future x when $p = 0$ or $\Delta = 0$. If P_t 's party will always stay in power, or if there is no conflict of interest between the party in power and the opposition, then P_t 's decision does not depend on what later presidents are expected to do. This is intuitive.¹³

Even if $p\Delta x = 0$, however, P_t 's decision is different from that of the first best because of the additional value $(\bar{b} - b)$ of exploitation for the party in power, and because θ_t can be different from the average shock (which is $\sigma/2$).

Part (ii) is intuitive as well: If P_t conserves, it is because P_t hopes to enjoy the conservation benefit c_P when the opposition rules. But if future presidents are likely to exploit, then P_t is more likely to exploit now if he fears to lose power ($p > 0$) and, with that, some of the gains (Δ) from exploiting the resource.

2.4. Equilibria

A stationary equilibrium is characterized by $x_t(x) = x$. For the equilibrium x to be unique and interior in (\underline{x}, \bar{x}) , we must have:

$$\theta(\underline{x}) > 0, \quad (\text{A1})$$

$$\theta(\bar{x}) < \sigma. \quad (\text{A2})$$

¹³The level of $x_t(x)$ is determined by the type that is indifferent between exploiting and conserving. The type that is indifferent now is also indifferent regarding whether his party will exploit later, and thus that later decision is of no consequence. Observation 1 in the Appendix elaborates on this.

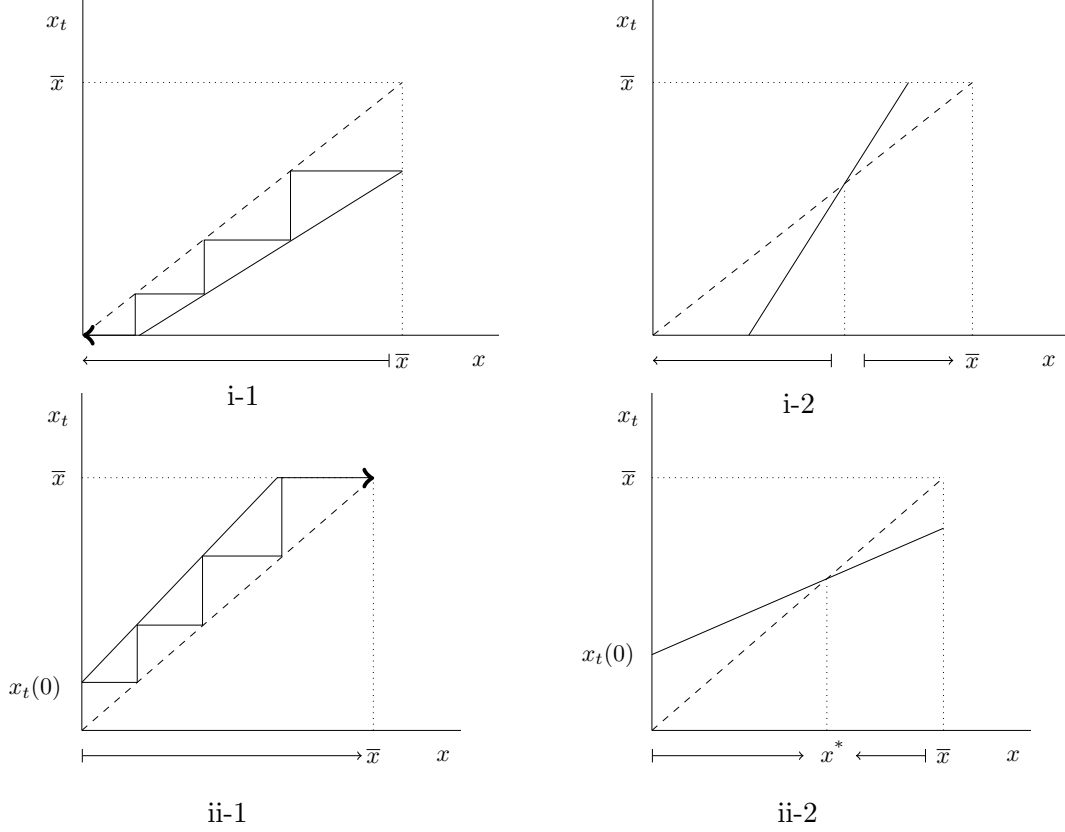

Figure 1: *In equilibrium, $x_t = x$.*

With (4)-(5), (A1) and (A2) are, respectively, equivalent to:

$$\begin{aligned}
 x_t(\underline{x}) > \underline{x} &\Leftrightarrow \delta p \Delta \underline{x} + (1 - \delta) \bar{b} > \underline{c}, \\
 x_t(\bar{x}) < \bar{x} &\Leftrightarrow \delta p \Delta \bar{x} + (1 - \delta) \bar{b} < \underline{c} + \sigma.
 \end{aligned}$$

All four cases are illustrated in Figure 1 and discussed in the following.

Self-fulfilling Expectations.—First, suppose \underline{c} is so large that (A1) fails: $\underline{c} > (1 - \delta) \bar{b} + \delta p \Delta \underline{x}$. If $\underline{x} = 0$, this inequality is simply $\frac{\underline{c}}{1 - \delta} > \bar{b}$. Under this condition, no president would ever exploit the resource if the probability (p) for the party to lose power were zero. Thus, the resource is never exploited in case (i-1) in Figure 1. If $p \Delta \bar{x}$ is large, (A2) fails and we enter case (i-2) and a situation with self-fulfilling expectations: While no president exploits if later presidents are expected to conserve, everyone exploits if it is expected that later presidents will exploit.

Unraveling.—Now, assume (A1) holds, so that there is always some chance that P_t prefers to exploit. If (A2) fails, the only equilibrium is $x = \bar{x}$. Remarkably, $x = \bar{x}$ is

the only equilibrium even if $x_t(0) > 0$ is arbitrarily small, i.e., if a long-lived party (that stayed in power with certainty) would exploit the resource with a tiny probability. The intuition for why $x = \bar{x}$ nevertheless is the only equilibrium is due to unraveling: If P_t is expected to exploit with a small but positive probability, then at time $t - 1$, exploitation becomes optimal for a set of θ_{t-1} 's so that the probability for exploitation at $t - 1$ is larger than the probability was at time t . Anticipating this, the incentive to exploit is even larger at time $t - 2$, and so on, until all incentives for conservation unravel and exploitation becomes attractive even for the most conservation-friendly president: see case (ii-1), Figure 1.

If both (A1) and (A2) hold, the domino effect converges. This situation is the relevant one if there is sufficient uncertainty and always some chance that the presidents may prefer to conserve, no matter what the future may bring, but it is also possible that some president, at some point in time, may prefer to exploit. When none of the possibilities can be ruled out, we are in case (ii-2), with the unique equilibrium outcome $x_t(x) = x \in (\underline{x}, \bar{x})$. Since only this equilibrium is sensitive to small changes in the parameters, it allows for particularly interesting comparative statics. To study them, I henceforth assume that (A1) and (A2) hold.

The Multiplier.—As one would expect, the probability of exploitation will be larger if \bar{b} is large and \underline{c} is small. More interestingly, while $x_t(0)$ measures the equilibrium probability for exploitation if $p = 0$, the equilibrium probability can be much larger when there is a chance ($p > 0$) that parties rotate being in office.

Proposition 2. *Suppose (A1) and (A2) hold. The equilibrium x is increasing in $p\Delta$:*

$$x = \frac{1}{1 - \delta p \Delta (\bar{x} - \underline{x}) / \sigma} \cdot x_t(0), \text{ where } \frac{1}{1 - \delta p \Delta (\bar{x} - \underline{x}) / \sigma} > 1 \text{ when } \delta p \Delta > 0. \quad (6)$$

The ratio $x/x_t(0) = 1/[1 - \delta p \Delta (\bar{x} - \underline{x}) / \sigma]$ can be referred to as the exploitation multiplier, since it measures the factor that $x_t(0)$ must be multiplied by in order to obtain the equilibrium x .

The exploitation multiplier can just as well be referred to as the conservation multiplier, since it coincides with the percentage increase in the probability of conservation $(1 - x)$ when the resource may be conserved also in the future, relative to the probability

Figure 2: A larger \bar{b} raises x all the way to x'' - thanks to the multiplier.

of conservation today if the resource were to be exploited in the very next period. Simple algebra verifies that:

$$\frac{1-x}{1-x_t(1)} = \frac{x}{x_t(0)} = \frac{1}{1-\delta p \Delta (\bar{x} - \underline{x}) / \sigma}.$$

The multiplier measures how x changes in parameters \underline{c} and \bar{b} , relative to how $x_t(0)$ changes in these parameters. This difference can be very large. Figure 2 illustrates that if \bar{b} increases, x increases from x^* to x'' even if the direct effect (for a fixed x) is simply $x'' - x'$.

The multiplier increases in $\bar{x} - \underline{x}$. Since $[\underline{x}, \bar{x}]$ can represent the discretion, or power, of the president, $\bar{x} - \underline{x}$ can be larger in countries with weak political institutions since various checks-and-balances often limit the power of the executive.

Threshold \underline{x} can also, as mentioned, reflect the minimal fraction (or probability) of extraction that we face, even if P_t attempts to conserve. For tropical deforestation, fires and illegal logging make it difficult to reduce x all the way to zero, but better monitoring technology can reduce \underline{x} . The upper boundary \bar{x} can be interpreted as the speed (or, alternatively, as the probability) at which exploitation may occur if P_t prefers to exploit the resource. For tropical forests, \bar{x} is limited by the capacity to log (which, in turn, is limited by the number of machines or specialized loggers). With technological progress, or economic development, deforestation can occur at a higher speed. Both technological changes make the multiplier more significant than it has been historically.

2.5. Extensions and Evidence

The theory predicts that the resource will be exploited faster than optimal, and especially fast with large political turnover rates, conflicts of interests, and discretion (i.e., with few checks and balances). Some of these predictions are in line with the evidence discussed in the Introduction (and Footnote 7). Simple extensions of the model verify that the present theory is also consistent with a number of other empirical facts.

Transition and Trade.—If a parameter shock, as the one in Figure 2, is unanticipated, then the equilibrium x jumps directly from x^* to x'' . Suppose, instead, it is anticipated that \bar{b} will increase at some time T . This expectation could be natural if a trade agreement, for example, would enter into force at that time. When P_{T-1} anticipates that P_T will exploit $x'' > x^*$, then P_{T-1} will exploit more, and as much as $x' \in (x^*, x'')$. When this $x' > x^*$ is anticipated by P_{T-2} , then P_{T-2} will also exploit more than x^* , and so on. Thus, there will be a gradual transition from x^* toward x'' , even before the parameter change has actually occurred. These increases are consistent with how deforestation has increased in the Brazilian Amazon in recent years, as discussed in the Introduction, even though Brazil's newly negotiated trade agreements (i.e., Mercosur's trade agreement negotiated with the EU and EFTA in 2019) have not yet been ratified.

Electoral Cycles.—Even though time is discrete in the model, it is easy to let time be continuous. Let ω be the length of each period, and ρ be the discount rate, so that $\delta = e^{-\rho\omega}$ continues to be the per-period discount factor. Consider a president of type $\theta_t \in (\theta(0), \theta(x))$, so that P_t will exploit, in equilibrium, even if he would not exploit if $p = 0$. Then, P_t prefers to exploit only at the end of his electoral period. This equilibrium choice leads to the electoral cycles of deforestation observed in Indonesia (Burgess et al., 2012) and in Brazil (Pailler, 2018).

Heterogeneous Parties.—If there are n identical parties, then $p = 1 - 1/n$. Thus, when a party is small (because n is large), x is larger. This insight holds if parties are heterogeneous: A minority party, once in power, will be more likely to exploit.

If parties are heterogeneous, we can also endogenize the reelection probability: When voters find x to be larger than they would prefer, then voters will be less likely to elect a minority party, because the minority party will be more likely to exploit. This choice,

in turn, reinforces the fact that the minority party receives few votes, and thus there can be multiple equilibria. The minority party will have an incentive to remove its handicap by depleting the resource as much as possible. That incentive, in turn, strengthens the conclusion that minority parties are more likely to exploit. This prediction fits well with the current situation in Brazil.¹⁴

This and other extensions are formally analyzed in the Online Appendix.

3. PAYMENTS AND LOBBYING FOR OR AGAINST EXPLOITATION

The above dynamic game between consecutive governments can be taken advantage of by external stakeholders. This section considers multiple principals who influence the presidents, and uncovers a fundamental inefficiency that arises when one stakeholder pays to maintain the status quo, while the other pays for exploitation. For pedagogical reasons, I introduce one stakeholder at the time.

3.1. Lobbying for Exploitation

Effects of Lobbying.—Agricultural sectors are often lobbying to get access to new land and it is reasonable to assume that their lobbying expenditures can persuade and benefit a president caving in to these requests. To start with, assume that the compensation is directly beneficial only for the president. Assume also that the lobby contribution l to P_t , conditional on exploitation at time t , enters linearly in P_t 's utility function. Then, P_t prefers to exploit when:

$$\bar{b} + l > c_p + \delta V^P = \underline{c} + \theta_t + \delta \frac{pbx + (1-p)\bar{b}x + (1-x)(\underline{c} + \theta_t)}{1 - \delta(1-x)} \Leftrightarrow$$

$$\theta_t < \theta_t(x) \equiv \delta p \Delta x + (1 - \delta) \bar{b} - \underline{c} + l [1 - \delta(1-x)]. \quad (7)$$

¹⁴After the election in 2018, *The Economist* wrote that "most analysts had thought that the right-winger would eventually lose to someone less divisive" and "his own Social Liberal Party, until now a tiny group, will have 52 seats in the 513-member lower house, up from eight in the outgoing congress." See <https://www.economist.com/the-americas/2018/10/13/jair-bolsonaro-is-poised-to-win-brazils-presidency>

When l increases, $\theta_l(x)$ increases and so does the likelihood of exploitation. With (7), replacing (4), $x_t(x)$ continues to be given by (5). That is, for any given future x , x_t increases in l . The increase in x_t is the immediate and direct effect of the lobbying.

There is also an indirect effect at play when l is expected to be offered to future presidents who exploit, since the larger future x contributes to a larger x_t , as observed in Proposition 1. Consequently, the total effect of a per-period payment l on x can be much larger than the effect of l , in period t only, on x_t . In other words, the presence and anticipation of future lobbying help the lobby to obtain what it seeks today (i.e., exploitation) at a lower cost. When l is paid to every future P_t who exploits, then, with (A1) and (A2), $x_t(x) = x$ implies that x^* is convex in l .¹⁵

$$x^* = \frac{\frac{\sigma x}{\bar{x}-x} + (1-\delta)\bar{b} - \underline{c} + (1-\delta)l}{\frac{\sigma}{\bar{x}-x} - \delta p\Delta - \delta l}. \quad (8)$$

Optimal Lobbying.—Suppose the exploitation lobby, E , is long-lived (the next section permits the lobby group to be less than long-lived). If E 's present-discounted value of succeeding with exploitation is represented by e , and E pays l to the president as soon as he exploits, E 's continuation value is:¹⁶

$$V^E = x(e-l) + (1-x)\delta V^E = \frac{x(e-l)}{1-\delta(1-x)}. \quad (9)$$

Proposition 3. *The optimal l , from E 's point of view, is:*

$$l^* \equiv \arg \max_l V^E = \max \left\{ 0, \frac{1}{2} \left[e - \frac{\sigma}{1-\delta} \frac{x}{\bar{x}-x} - \bar{b} + \frac{\underline{c}}{1-\delta} \right] \right\}. \quad (10)$$

¹⁵(A1) and (A2) imply that x^* is interior in $[\underline{x}, \bar{x}]$. Section 4 studies a corner solution.

¹⁶As in Section 2.2, x can be interpreted as the expected fraction that is extracted from a stock of resource. In that situation, l should be interpreted as the payment per unit of resource that is exploited, e is E 's value per unit of extraction, and V^E is E 's continuation payoff per unit of the resource. With this, the stock size S_t cancels from the relevant expressions and first-order conditions, as in Section 2. For example, E 's continuation payoff can be written as:

$$S_t V^E = x S_t (e-l) + (1-x) S_t \delta V^E = \frac{x(e-l)}{1-\delta(1-x)} S_t$$

which is equivalent to (9). The same cancellation applies when we introduce the second principal in Section 3.2.

Intuitively, and as evident from the first two terms in (12), l^* increases in e and in $(\bar{x} - \underline{x})$. So, l^* increases regardless of whether P_t has access to more effective exploitation technology or conservation technology – or if institutions are weak. As long as \bar{x} is large or \underline{x} is small, P_t 's decision matters more to E .

The optimal l^* is smaller when $(1 - \delta)\bar{b} - \underline{c}$ is large because, in this case, it is more likely that P_t exploits even without the transfer.

3.2. *Compensating for Conservation*

Effects of Compensations.—If a compensation k is paid to P_t conditional on conservation, the effect of k on x_t is exactly as in (5) if l in (7) is replaced by $-k$. This is intuitive, since k is a payment for the opposite of l .

If k will be paid to the president in any period with conservation, then $x_t = x$ will be given by (8), as before, if just l is replaced by $-k$. Even though $x_t(x)$ is linear in k , $1 - x$ is convex in k . Once again, the multiplier is at play: When P_t anticipates that future compensations will reduce x , then P_t becomes more willing to conserve at time t because of the reduced future x as well as because of the possibility to obtain k right now. In other words, the presence (and anticipation) of future compensations helps the donor obtain what it seeks today (i.e., conservation) at a lower cost.

Optimal Compensation.—Let D ("she") be a long-lived donor and $d > 0$ the per-period damage avoided in every period in which the resource is conserved. With a linear per-period cost of k , D 's continuation payoff is:

$$V^D = (1 - x)(d - k + \delta V^D) = \frac{(1 - x)(d - k)}{1 - \delta(1 - x)}. \quad (11)$$

Proposition 4. *The optimal $k \geq 0$, from D 's point of view, increases in $p\Delta$:*

$$k^* \equiv \arg \max_k V^D = \max \left\{ 0, \frac{1}{2} \left[d - \sigma \frac{1 - \underline{x}}{\bar{x} - \underline{x}} + (1 - \delta)\bar{b} - \underline{c} + \delta p\Delta \right] \right\}. \quad (12)$$

Once again, the stakeholder pays more when the stake (here, d) is large and P_t has a lot of discretion (in that $\bar{x} - \underline{x}$ is large).

However, in contrast to E , D pays less when $\bar{b} - \frac{\underline{c}}{1-\delta}$ is small because P_t is then quite likely to conserve in any case and k leads to less additional conservation.

Note the final term in (12), $\delta p\Delta$, which increases with the multiplier. This term implies that the larger is the multiplier, the larger is the optimal k^* . Simply put: It is optimal to offer more for conservation if the party in power is likely to lose power in the future, or if the disagreement between the ruling party and the opposition is large. The intuition is that a larger multiplier makes the decision more sensitive to small changes in the parameters.

3.3. *Paying (forever) for Conservation vs. (once) for Exploitation*

It is easy to see (and the Appendix proves) that when D bids for conservation, and E simultaneously bids for exploitation, then the two optimal best-response functions are interdependent:

$$k^* = \max \left\{ 0, \frac{1}{2} \left[l + d - \sigma \frac{1-x}{\bar{x}-x} + \delta p\Delta + (1-\delta)\bar{b} - \underline{c} \right] \right\}, \quad (13)$$

$$l^* = \max \left\{ 0, \frac{1}{2} \left[k + e - \frac{\sigma}{1-\delta} \frac{x}{\bar{x}-x} - \bar{b} + \frac{\underline{c}}{1-\delta} \right] \right\}. \quad (14)$$

Although the presence of lobbying makes it less likely that P_t will conserve, given any k , lobbying is nevertheless increasing the optimal k^* . Intuitively, with lobbying, the payment for conservation is less likely to be wasted on conservation that would have taken place regardless. Analogously, compensations for conservation increase the necessity to lobby, and the equilibrium lobby contributions increase.

The equilibrium $x_t(x)$ continues to be given by (5) if just (4) is replaced by:

$$\theta_{kl}(x) \equiv \delta p\Delta x + (1-\delta)\bar{b} - \underline{c} - (k^* - l^*)[1 - \delta(1-x)]. \quad (15)$$

If we henceforth assume both k^* and l^* are strictly positive, then the total effect of both payments on x^* is given by the following result.

Figure 3: Suppose $d/e \in (1 - \delta, 1)$, and that d and e increase by the same proportion. Then, $e - d$ increases, and x^* increases, but $e - d / (1 - \delta)$ decreases, and the first-best x declines (dashed line).

Proposition 5. *The equilibrium x^* increases in $e - d$:*

$$x^* = \frac{\frac{\sigma x}{\bar{x} - x} + (1 - \delta) \bar{b} - \underline{c} + (1 - \delta) (l^* - k^*)}{\frac{\sigma}{\bar{x} - x} - \delta p \Delta - \delta (l^* - k^*)}, \text{ where} \quad (16)$$

$$l^* - k^* = \frac{1}{3} \left[e - d + \frac{\sigma}{\bar{x} - x} \left(1 - x \left(\frac{2 - \delta}{1 - \delta} \right) \right) - (2 - \delta) \bar{b} + \underline{c} \left(\frac{2 - \delta}{1 - \delta} \right) - \delta p \Delta \right].$$

Inefficiency.—At first, it may appear intuitive that d and e enter symmetrically in $k - l$, and thus in x . However, while e is E 's present discounted value when the resource is exploited, and the land is forever accessible to agriculture, d is the *per-period flow* payoff to D from conservation. The present-discounted value of conservation forever is $d / (1 - \delta) > d$. With D and E , the criterion for when it is socially optimal to exploit changes from (1) to:

$$e + b > \frac{c + d}{1 - \delta}. \quad (17)$$

Thus, if $d/e \in (1 - \delta, 1)$, the presence of D and E makes conservation more likely to be efficient, but, in equilibrium, their payments increase x . In particular, suppose d and e increase by the same proportion, so that the ratio remains constant, $d/e \in (1 - \delta, 1)$. With these changes, $e - d$ increases and the resource will be exploited, even though (17)

will eventually fail, i.e., the first best, x^{FB} , is reduced, as illustrated by the dashed line in Figure 3.

Corollary to Proposition 5. *Suppose d and e increase by the same proportions, so that $d/e \in (1 - \delta, 1)$ stays fixed. Eventually, it becomes socially optimal to conserve, but in equilibrium $l - k$ increases and so does x .*

The intuition for this inefficiency is that E needs to pay only one single time for exploitation, while D needs to pay every future P_t for conservation. The future payments, to the later presidents, are costly for D but not directly appreciated by the current president.

Time Inconsistency and Markov Strategies.—For pedagogical reasons, the analysis above has considered D 's and E 's optimal time-invariant payments. Section 5 proves that similar results hold if all strategies must be Markov perfect. With Markov-perfect strategies, each payment is smaller than if the principal can commit (see Propositions 8 and 9), but the equilibrium x , referred to as x^M , continues to be linear and increasing in $e - d$, exactly as illustrated in Figure 3 (see Proposition 10 and its proof).

So far, the analysis has been positive: Section 2.5 argued that the basic political-economy model is consistent with several facts. The inefficiency derived in this section is also in line with the evidence.¹⁷ The consistency with evidence makes the following normative analysis meaningful.

¹⁷Section 3.3 suggests that exploitation can be ineffectively large, even when the donor offers compensations in return for conservation. After more than a decade with REDD+, deforestation has increased in Brazil, as discussed in the Introduction. Overall, the evidence is mixed, at best: IPBES (2019:54) reports that "the literature is currently mixed on the success rates of forest carbon projects in general and REDD+ has faced a number of challenges."

4. COST-EFFECTIVE CONSERVATION

There is an intense debate regarding whether compensations for conservation should be earmarked and how they should be targeted (Angelsen et al., 2018). The fundamental inefficiency illustrated in the previous section suggests that paying the presidents may not necessarily be the best way of achieving conservation. It might be less expensive for D to pay in terms of public goods, or party goods, that increase P_t 's conservation value even after he retires as president. It may also be more efficient for D to pay E for reducing its lobby effort, than to pay every president in competition with E .

To study such targets in a pedagogic setting, it will be assumed that $d - e$ is so large that D conserves in full: $x = \underline{x}$, where $\underline{x} = 0$. This corner solution is relevant because the value of conserving tropical forests vastly exceeds the benefits of logging, as was argued in the Introduction. (Observation 4 in the Appendix presents the exact condition under which $x = \underline{x}$ is optimal. The Online Appendix lets D face budget constraints.)

4.1. *Paying Presidents, Parties, or the Public*

Paying the Public.—If D pays for conservation and this payment is earmarked for a public good, the current president benefits directly from future conservation payments, and not only from the indirect effect through the reduced x . With this, the president is incentivized to conserve more now. On the other hand, paying for public goods is less targeted toward the president, since the funds are tied to goods that may be of secondary importance to the president (with direct transfers to the president, the president can spend the money on public goods, or on private perks, just as the president pleases).

To capture this trade-off, suppose D 's per-period payment k_G , conditional on conservation, provides the benefit $\gamma > 0$ per dollar for the opposition as well as for the party in power. It is reasonable that $\gamma < 1$, since, otherwise, the president (whose value of a dollar is normalized to 1) would prefer to spend his private funds on the public good. Note that γk_G has a role similar to that of the conservation benefit \underline{c} , and that the equation for x continues to hold if just \underline{c} is replaced by $\underline{c} + \gamma k_G$.

Paying Parties.—Payments to the president, and earmarks to a public good, are both extreme cases. An intermediate case is that D offers a transfer, k_R , to be administered by the ruling party, so that each dollar gives everyone associated with the ruling party some benefit $\alpha > 0$. It is reasonable that $\alpha > \gamma$, since the party would otherwise prefer to spend all party dollars on the public good. It is also reasonable that $\alpha < 1$, since, otherwise, the president would prefer to transfer his private funds to the party. In this intermediate case, the current president receives the direct benefit αk_R from conserving today. When it is anticipated that these transfers will arrive also in later periods, the correspondingly lower future x gives the current president an indirect benefit from conserving now. As a third effect, the current president's expected direct benefit of later conservation is $(1 - p) \alpha k_R$.

With these modifications, the resource is exploited at time t if and only if:

$$\theta_t < \theta_R(x) \equiv \delta p \Delta x + (1 - \delta) \bar{b} - \underline{c} - \gamma k_G - \alpha k_R [1 - \delta p (1 - x)] - (k - l) [1 - \delta (1 - x)].$$

To guarantee least-cost conservation, D 's problem is:

$$\min_{k \geq 0, k_R \geq 0, k_G \geq 0} (k + k_R + k_G) \text{ s.t. } \theta_R(0) = 0. \quad (18)$$

The solution to D 's problem is always a corner solution with payments only to the president, the party, or the public, as illustrated in Figure 4.

Proposition 6. *To ensure maximal conservation ($x = 0$), it is optimal for D to pay*
(i) the public if δ is large:

$$\gamma \geq \max \{1 - \delta, \alpha (1 - \delta p)\}. \quad (19)$$

(ii) the party if p is small:

$$\alpha (1 - \delta p) \geq \max \{\gamma, 1 - \delta\}, \quad (20)$$

(iii) the president otherwise, i.e., if:

$$1 - \delta > \max \{\gamma, \alpha (1 - \delta p)\}. \quad (21)$$

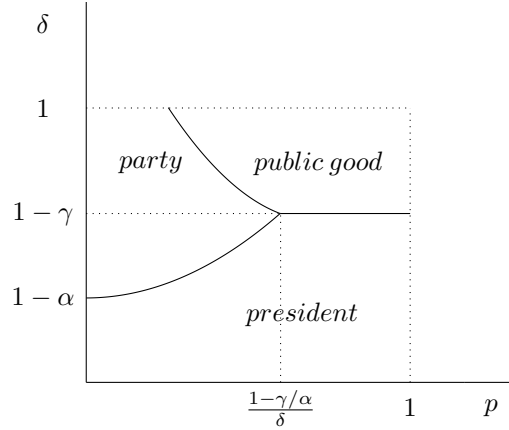

Figure 4: D benefits from earmarking the funds to public goods if δ is large, but from giving the ruling party discretion over the funds if p is small.

Compensating the public can be best for D since then P_t benefits directly when future presidents can conserve. This solution is more likely to be best if δ , the weight on future benefits, is large. Allowing the ruling party to spend the money as it pleases is also giving the current P_t direct benefits if his party's future presidents can conserve. This benefit is large only when p , the probability of losing power, is small. Thus, a more stable political environment means that letting parties administer the funds can be best.

The impacts of the valuation parameters α and γ for the comparison are straightforward.

In contrast to D , E would never prefer to direct funds to the party or the public, instead of to the president directly, as long as $\alpha < 1$ and $\gamma < 1$. Such payments are not only less effective right now, but they also increase P_t 's value of postponing exploitation, making immediate exploitation less likely

Note that the level of l is irrelevant for the result – Proposition 6 holds for any l – as long as l is the same regardless of how D pays. And, indeed, the equilibrium l is the same regardless of (i)-(iii): When $x \downarrow 0$, E 's optimal choice is always $l \uparrow e$, as shown in the Appendix.¹⁸

¹⁸It is assumed that E does not significantly benefit directly from any of the transfers k , k_R , or k_G , even though k_G is referred to as a public good. After all, the value of land, e , is likely to be much larger.

4.2. Paying the Lobby

Compensating short-lived presidents is expensive because D must compensate every one of them for not exploiting a resource. If the lobby group is long-lived, then it can be less expensive to pay E to not lobby, since E anticipates that it can lobby or receive compensations also next period.

Let $q \in [0, 1]$ measure the probability that E will *not* be the relevant lobby group in any future period. (This will not change the previous result.) With probability $1 - q$, the current lobby group can lobby in order to obtain e also in later periods. With probability q , E 's lobby power is replaced by another (identical) group. To treat E and D more or less symmetrically, the reader is free to restrict attention to $q = 0$, as has been done so far. Alternatively, the lobby group and the party in power will be more similar if $q = p$. If $q < p$, the lobby group is more likely to be a player in the future than is the political party in power.

As above, if $x \downarrow 0$, then l increases toward E 's value of exploitation, which is e when D does not pay E . If D pays $k_E \geq 0$ to discourage E from lobbying, then E 's value of exploitation is reduced because E will subsequently lose the payments from D . The reduced value means that E finds it optimal to reduce l , even if we assume that l is unobservable for D , so that D can condition her payments to E only on whether the resource is exploited and not on the level of l .¹⁹

If D pays the relevant lobby group an amount $k_E \geq 0$ in every period with conservation, E 's net value of exploitation is reduced from e to $e - \frac{k_E}{1-\delta(1-q)}$, given the present-discounted value of the per-period k_E . When $x = 0$, the optimal l is also reduced by this

¹⁹In principle, we can here proceed by making one of the following alternative assumptions:

(a) We may assume that D can observe l so that, if E selects $l > 0$ in this period, E does not receive k_E in this period and, with probability x , E receives e and the game ends.

(b) D may be unable to observe l . Thus, if the resource is not exploited, E receives k_E and the game continues. If the resource is exploited, then E receives e instead of the flow of k_E every period.

(c) E might, with some chance, learn θ_t before E decides to lobby to receive e . As in case (b), the consequence for E is that E loses the flow of k_E every period if and only if P_t exploits. (In this case, it will not matter whether D observes l .)

I have decided to focus on case (b) because (i) it leads to the same outcome as case (c), (ii) this outcome is simpler to describe than the outcome in (a), (iii) the payment following (b) and (c) is larger than under (a) and thus it is robust and sufficient regardless of whether E observes θ_t , or D observes l , and (iv) if D benefits from paying E in cases (b) and (c), then she also benefits from this payment in case (a) (since the payments are then less).

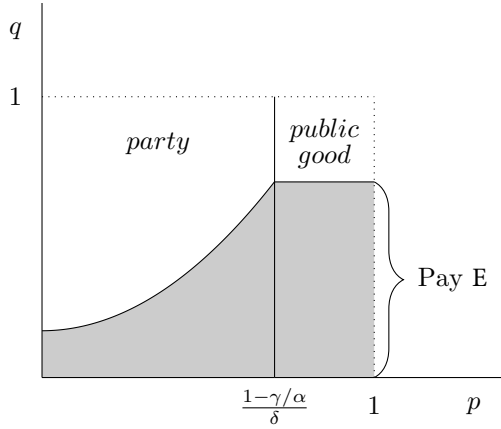

Figure 5: D benefits from paying E to abstain from lobbying if q is small while p is large.

amount. When this term is substituted in the expression for $\theta_R(0)$ (replacing e), and D solves $\min(k + k_R + k_G + k_E)$ s.t. $\theta_R(0) = 0$, we can see that it is optimal with either $k_E = 0$ or

$$k_E = e [1 - \delta (1 - q)], \quad (22)$$

so that E , in that case, prefers $l = 0$. This exercise also leads to the next proposition.

Proposition 7. D benefits from paying E to not lobby if q is small and p large. The following three cases correspond to the cases in Proposition 6:

(i) Suppose (19) holds. D benefits from paying E to not lobby if and only if:

$$q < \frac{1 - \delta}{\delta} \frac{1 - \gamma}{\gamma}.$$

(ii) Suppose (20) holds. D benefits from paying E to not lobby if and only if:

$$q < \frac{1 - \delta}{\delta} \frac{1 - (1 - \delta p) \alpha}{(1 - \delta p) \alpha}.$$

(iii) Suppose (21) holds. D always benefits from paying E to not lobby, and strictly so if $q < 1$.

It is quite intuitive that D prefers to pay E when q is small and p is large. If q is

small, E appreciates not only the current compensation from D , but also the expected payments in the future. In this case, the per-period payment k_E is effective in persuading E to not lobby. If p is small, P_t appreciates future payments to the party, so then k_R may reduce x more than k_E can, especially if q is large. Parts (i) and (ii) of the proposition are illustrated in Figure 5. (In the figure, it is assumed that $1 - \delta < \gamma$, so that it is never optimal to pay the president directly.)

When it is optimal for D to pay E to not lobby, then D pays as much as is needed to ensure that either $x^* = 0$ or $l^* = 0$. If the first constraint binds first, so that $k_E = e$ is sufficient to ensure that $x^* = 0$, then D pays E only, and not the president, the party, or the public.

5. TIME INCONCISTENCY AND MARKOV STRATEGIES

For pedagogical reasons, it has so far been assumed that D decides on a time-invariant k , while E decides on a time-invariant l . In this case, each principal might take advantage of the multiplier by committing to a large payment, since the payment at time $\tau > t$ is influencing not only x_τ , but also x_t because of the multiplier effect. If the principals cannot commit, and payments must be Markov perfect, then the equilibrium payment levels will be different but the above insights survive as follows. (The Online Appendix considers other SPEs.)

The Lobby. To begin, consider the situation in Section 3.1 with only one principal. Suppose E can commit to l_t only, at the beginning of period t , before observing θ_t , and that E cannot affect actual or expected future compensation levels (i.e., E 's strategy must be Markov perfect). Any effect of l_t on earlier decisions is sunk, making it less beneficial for E to raise l_t as much as E preferred when E decided on a time-invariant l . Consequently, the MPE l_t , call it l^M , is smaller than l^* .

Proposition 8. *There exists an MPE, s.t. E pays $l^M \leq l^*$ when P_t exploits, if and only if:*

$$l^M = \max \left\{ 0, l^* - \frac{x^M \theta'_l}{2(1-\delta)} \right\}, \text{ where } \theta'_l = \delta(p\Delta + l) > 0.$$

For simplicity, and to facilitate the comparison, l^M is defined relative to l^* . The result is then intuitive: The reason E would like to commit to a large l^* is that less exploitation

in the future influences x_t . The larger this influence is (i.e., θ'_t), the larger the difference between l^* and l^M is.

If $x^M \rightarrow 0$, $l^M \rightarrow e$ whether or not E commits, so then the difference $l^* - l^M$ vanishes. (Observation 2 in the Appendix elaborates.)

The Donor. Consider now the situation in Section 3.2, with D as the only principal, and suppose she can commit to k_t only, at the beginning of period t , before observing θ_t , and that she cannot affect actual or expected future compensation levels. Any positive effect of k_t on earlier x 's is sunk, making it less beneficial for D to raise k_t as much as D preferred when D decided on a time-invariant k . Consequently, the MPE k_t , call it k^M , can be smaller than k^* .²⁰

Proposition 9. *Suppose $\partial\theta_k(x^M)/\partial x^M > 0$. There exists an MPE, s.t. D pays $k^M \leq k^*$ when P_t conserves, if and only if:*

$$k^M = \max \left\{ 0, k^* - \frac{(1 - x^M) \theta'_k}{2} \right\}, \text{ where} \quad (23)$$

$$\theta'_k \equiv \partial\theta_k(x^M)/\partial x^M = \delta(p\Delta - k^M).$$

The difference is intuitive: The reason D would like to commit to a large k^* is that less exploitation in the future influences x_t . The larger this influence is (i.e., θ'_k), the larger the difference between k^* and k^M is.²¹

If $x^M \rightarrow 1$, $k \rightarrow d$ regardless of whether D commits or not, so then the difference $k^* - k^M$ vanishes. (Observation 3 in the Appendix elaborates.)

We may want to write $x^M(k)$, to remind us that x^M depends on k . And, because θ'_k is also a (decreasing) function of k^M , Proposition 9 admits two pure-strategy equilibria when (23) holds for $k_M = k^* - (1 - x^M(k_M)) \delta(p\Delta - k^M)/2 > 0$ and if also $k^* - (1 - x^M(0)) \delta p\Delta/2 < 0$, which permits $k^M = 0$. This multiplicity is natural, because the optimal k_t depends on the expected k in the future: Intuitively, it may be too expensive to persuade P_t to conserve if P_t expects no future payments and thus a large x^M .

²⁰For simplicity, and to facilitate a comparison, k^M is defined relative to k^* . An explicit equation for k^M is derived in the Appendix.

²¹If k^M is so large that $\theta'_k = \delta(p\Delta - k^M) < 0$, then the president at time t considers future presidents to be paid to conserve too much. In this case, a smaller x increases x_t , and D would like to commit to a smaller future k . This possibility is related to the discussed of $\Delta < 0$ in the Online Appendix.

Two Principals.—With both principals, and Markov-perfect strategies, x^* continues to be given by (16) if just $k^* - l^*$ is replaced by $k^M - l^M$.²² The change in x^* is ambiguous: As noted above, $|k^* - k^M|$ is small if x^M is small, while $|l^* - l^M|$ is small if x^M is large. The Appendix contains the proof of the following comparison (consistent with the illustration in Figure 3):

Proposition 10. *Suppose $\theta'_{kl} > 0$. We have $x^M > x^*$, and $l^M - k^M > l^* - k^*$, if and only if*

$$x^* < \frac{1 - \delta}{2 - \delta}.$$

Paying Presidents, Parties, or the Public. In Section 4.1, D could benefit from earmarking the funds to the party or to the public good, instead of paying the president personally, because then the current president will benefit directly from future compensations, in addition to the indirect effect through x . This benefit requires that P_t can trust that D will continue with this earmarking also in later period. D will need to establish a reputation for this earmarking (or D will need some other kind of commitment technology), because in any given period, D is tempted to pay P_t directly as long as $\alpha < 1$ and $\gamma < 1$.

Note that E does not face this time inconsistency problem: E would prefer to pay P_t personally whether or not E can commit to this strategy as long as $\alpha < 1$ and $\gamma < 1$.

Paying the Lobby. When D 's strategy must be Markov perfect, then case (iii) is the relevant one in Proposition 7 as well as in Proposition 6. In this case, Proposition 7 states that D is always better off paying E to not lobby, instead of only paying P_t personally. This conclusion continues to hold when D 's strategy is Markov perfect. The reason is that when D pays the presidents personally, future payments are not directly beneficial to P_t , so it is quite expensive for D to persuade P_t to conserve. If, instead, D pays E to not lobby, then E benefits directly from conservation because E can always lobby for exploitation (or receive payments) in later period: this benefit is strictly positive as long as $q < 1$. Thus, even if strategies must be Markov perfect, a robust conclusion is that the donor benefits from paying the lobby group to not lobby – instead of paying directly to a short-lived president.

²²As shown in the Appendix, k^M and l^M are inter-dependent in a similar way as k^* and l^* are.

6. CONCLUDING REMARKS

This paper provides a positive theory for the game between consecutive governments when each of them decides whether to exploit or conserve a resource, such as a tropical forest. Because the current decision depends on expected future policies, parameter changes have a multiplier effect. The framework is employed to show how a lobby group, eager to exploit, can take advantage of the multiplier. A donor, interested in conservation, can also benefit from the multiplier, but the asymmetry between paying once for exploitation vs. forever for conservation leads to an inefficient outcome.

The framework can be applied to alternative contexts but, more specifically, the predictions are consistent with recent developments in Brazil: Although earlier governments have succeeded in reducing deforestation, the current government facilitates deforestation. The current government is unlikely to stay in power in the future (given its sagging popularity and historically bad polls), so it is in line with the predictions that it prefers exploitation rather than conservation. The prospects of new international trade agreements, signed with the EU, US, and EFTA, make it plausible that deforestation will eventually occur, in any case. Anticipating all this, the government benefits from permitting deforestation already now.

The results also provide a number of normative policy implications. First, payments contingent on conservation can have dramatically large effects because of the multiplier. Second, the anticipation of future payments, and the trust that they will continue to be offered, may have larger effects than the contemporary effects of current payments. It is thus essential to build credibility that payments will continue. Third, it is tempting for the donor to offer funds that can be used at the discretion of the president, but it may be more effective to build a reputation for earmarking the funds for public goods, beneficial also for parties no longer in power. Finally, if the lobby group, willing to pay for exploitation, is more of a long-run player than is the current political party in power, then cost-effective conservation requires the donor to compensate the lobby for halting its lobbying effort.

APPENDIX: PROOFS

Notation: To facilitate the later proofs, all proofs allow for a payment k to P_t if P_t conserves, and a payment l when he exploits, as discussed in Section 3. Furthermore: I will permit the value of conservation in the future to be different for P_t when P_t 's party is in power, than when he is not in power. In particular, P_t 's value of conservation whenever P_t 's party is not in power is $c_P = \underline{c} + \theta_t$, while P_t 's value of conservation is \widehat{c}_P whenever P_t 's party is in power, where $\widehat{c}_P = \widehat{c} + \theta_t$, $\widehat{c} = \underline{c} + f$, and f can be positive or negative. The results in Section 2 follow by requiring $k = l = f = \widehat{c} - \underline{c} = 0$. I also use the simplification $\widetilde{\sigma} \equiv \frac{\sigma}{\bar{x} - x}$ and $\varphi \equiv k - l$.

Proof of Lemma 1:

For s_t to be Markov perfect, s_t , and thus x , cannot be functions of the stock when the stock is payoff irrelevant. The stock is payoff irrelevant as long as when later presidents do not condition their strategies on the stock, then the current president does not benefit from conditioning s_t on S_t . To see that the stock is indeed payoff irrelevant, note that if the future x is constant over time, then $S_\tau = (1 - x)^{\tau - t} S_t$ and P_t 's continuation value at $\tau > t$ can be written as:

$$\begin{aligned} & \sum_{\kappa=\tau}^{\infty} \delta^{\kappa-\tau} [pbxS_\kappa + (1-p)\bar{b}xS_\kappa + (1-x)S_\kappa c_P] \\ &= \sum_{\kappa=\tau}^{\infty} \delta^{\kappa-\tau} (1-x)^{\kappa-\tau} S_\tau [pbx + (1-p)\bar{b}x + (1-x)c_P] \\ &= S_\tau \frac{pbx + (1-p)\bar{b}x + (1-x)c_P}{1 - \delta(1-x)} = S_\tau V^P, \end{aligned}$$

where V^P is as in (2). Anticipating this, P_t solves:

$$\arg \max_{s_t \in [x, \bar{x}]} s_t S_t \bar{b} + (1 - s_t) S_t c_P + \delta (1 - s_t) S_t V^P,$$

which is independent of S_t and coinciding with s_t in (3). *QED*

Proof of Proposition 1:

P_t receives \bar{b} if he cuts now. Suppose that if P_t does not cut now, then his party will cut with probability y any later period it is in power, while the opposition exploits with probability x any period P_t 's party is not in power. With this, the current P_t 's continuation value at the beginning of any later period, $\tau > t$, is:

$$\begin{aligned} V^P &= (1-p)y\bar{b} + pxb + (1-p)(1-y)(\widehat{c}_P + \delta V^P) + p(1-x)(c_P + \delta V^P) \\ &= \frac{(1-p)y\bar{b} + pxb + (1-p)(1-y)\widehat{c}_P + p(1-x)c_P}{1 - \delta(1-p)(1-y) - \delta p(1-x)}. \end{aligned}$$

The numerator as well as the denominator are clearly positive. Therefore, P_t prefers to cut

now if:

$$\begin{aligned}
& k + \widehat{c}_P + \delta V^P < \bar{b} + l \Leftrightarrow \\
& k + \widehat{c}_P + \delta \frac{(1-p)y\bar{b} + pxb + (1-p)(1-y)\widehat{c}_P + p(1-x)c_P}{1 - \delta(1-p)(1-y) - \delta p(1-x)} < \bar{b} + l \Leftrightarrow \\
& (1-p)y\bar{b} + pxb + (1-p)(1-y)(\widehat{c} + \theta_t) + p(1-x)(\underline{c} + \theta_t) < \\
& \frac{1}{\delta} (\bar{b} + l - k - \widehat{c} - \theta_t) [1 - \delta(1-p)(1-y) - \delta p(1-x)] \Leftrightarrow \\
& \theta_t < \theta(x) \equiv (1-\delta)\bar{b} - \widehat{c} + \delta p\Delta x + \delta p(1-x)f \\
& \quad + (l-k)[1 - \delta(1-p)(1-y) - \delta p(1-x)].
\end{aligned}$$

Observation 1: If $l = k$, $\theta(x)$ depends on x , but not on y .

So, when there is neither lobbying nor donations, then the level of y is not relevant for P_t 's decision. This is natural, since if P_t is indifferent now, he is indifferent later, and thus to his own party's choice of y , as well.

Even if we do not impose $l = k$, $\theta(x)$ simplifies to the following when $y = x$:

$$\theta(x) = (1-\delta)\bar{b} - \widehat{c} + \delta p\Delta x + \delta p(1-x)f + (l-k)[1 - \delta(1-x)], \quad (24)$$

which, in turn, simplifies to (4) when $f = l - k = 0$.

The probability that P_t prefers to exploit is:

$$0 \text{ if } \theta(x) \leq 0, \theta(x)/\sigma \text{ if } \theta(x) \in [0, \sigma], \text{ and } 1 \text{ if } \theta(x) \geq \sigma.$$

If P_t prefers to (not) exploit, he exploits with probability $\bar{x}(\underline{x})$. Thus, the probability for exploitation is

$$x_t(x) = \bar{x} \cdot \frac{\theta(x)}{\sigma} + \underline{x} \cdot \left(1 - \frac{\theta(x)}{\sigma}\right) = \underline{x} + (\bar{x} - \underline{x}) \cdot \frac{\theta(x)}{\sigma}, \quad (25)$$

if $\theta(x) \in [0, \sigma]$, while $x_t(x) = \underline{x}$ if $\theta(x) < 0$ and $x_t(x) = \bar{x}$ if $\theta(x) > \sigma$. This can be written as (5). *QED*

Proof of Proposition 2:

Note, first, that the three first cases in Fig.1 are trivial. (A1) and (A2) are, respectively, more generally written as:

$$\begin{aligned}
\theta(\underline{x}) > 0 & \Leftrightarrow (1-\delta)\bar{b} - \widehat{c} + \delta p(1-\underline{x})f + (l-k)[1 - \delta(1-\underline{x})] > \underline{x}(\sigma - \delta p\Delta), \\
\theta(\bar{x}) < \sigma & \Leftrightarrow (1-\delta)\bar{b} - \widehat{c} + \delta p(1-\bar{x})f + (l-k)[1 - \delta(1-\bar{x})] < \bar{x}(\sigma - \delta p\Delta).
\end{aligned}$$

When both hold (case ii-2), there exists, by continuity, $x \in [\underline{x}, \bar{x}]$ such that $x_t(x) = x$. To find this fixed point, substitute in for $\theta(x)$ and $x_t(x) = y = x$ in (25) and solve for x to obtain:

$$x = \frac{\tilde{\sigma}\underline{x} + (1-\delta)\bar{b} - \underline{c} - f(1-\delta p) + (1-\delta)(l-k)}{\tilde{\sigma} - \delta p(\Delta - f) - \delta(l-k)}. \quad (26)$$

With $f = l - k = 0$, we arrive at (6). *QED*

Proof of Proposition 3:

First, notice that the following expression is linear in l :

$$\begin{aligned} \frac{x}{1 - \delta(1 - x)} &= \frac{\tilde{\sigma}\underline{x} + (1 - \delta)\bar{b} - \hat{c} + \delta pf + (1 - \delta)(l - k)}{(1 - \delta)[\tilde{\sigma} - \delta p(\Delta - f) + \delta\varphi] + \delta[\tilde{\sigma}\underline{x} + (1 - \delta)\bar{b} - \hat{c} + \delta pf - (1 - \delta)\varphi]} \\ &= \frac{\tilde{\sigma}\underline{x} + (1 - \delta)\bar{b} - \hat{c} + \delta pf + (1 - \delta)(l - k)}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \hat{c}] - \delta(1 - \delta)p\Delta + \delta pf}. \end{aligned}$$

Since this expression is linear in l , it is straightforward to maximize (9) and derive the optimal l . The f.o.c. w.r.t. $l \geq 0$ is (the s.o.c. holds trivially):

$$(e - l) \frac{\partial}{\partial l} \frac{x}{1 - \delta(1 - x)} - \frac{x}{1 - \delta(1 - x)} \leq 0.$$

Observation 2: If $x \downarrow 0$, this first-order condition requires $l \uparrow e$.

Otherwise, the f.o.c. can be written as:

$$(1 - \delta)(e - l) - [\tilde{\sigma}\underline{x} + (1 - \delta)\bar{b} - \hat{c} + \delta pf + (1 - \delta)(l - k)] \leq 0, \quad (27)$$

with equality if $l > 0$ and if the corresponding $x < \bar{x}$. With $\hat{c} = \underline{c}$ and $k = f = 0$, we arrive at (10).

However, note that we obtain a corner solution with $x = \bar{x}$ if (27) is positive at such a large l . From (24), we see that the required l is determined by:

$$\begin{aligned} \theta_k(\bar{x}) &= (1 - \delta)\bar{b} - \hat{c} + \delta p\Delta\bar{x} + \delta p(1 - \bar{x})f + (l - k)[1 - \delta(1 - \bar{x})] = \sigma \Leftrightarrow \\ (l - k)[1 - \delta(1 - \bar{x})] &= \sigma - (1 - \delta)\bar{b} + \hat{c} - \delta p\Delta\bar{x} - \delta p(1 - \bar{x})f. \end{aligned}$$

At this l , (27) is indeed positive if

$$\begin{aligned} (1 - \delta)e - 2(1 - \delta) \frac{\sigma - (1 - \delta)\bar{b} + \hat{c} - \delta p\Delta\bar{x} - \delta p(1 - \bar{x})f}{1 - \delta(1 - \bar{x})} \\ > \tilde{\sigma}\underline{x} + (1 - \delta)\bar{b} - \hat{c} + \delta pf + (1 - \delta)k. \end{aligned}$$

So, for such a large e , (A1) fails and E pays so much that $x = \bar{x}$. *QED*

Proof of Proposition 4:

First, note that, with (26), and with the simplified notation $\varphi \equiv k - l$, the following expression is linear in k :

$$\begin{aligned} \frac{1 - x}{1 - \delta(1 - x)} &= \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p(\Delta - f) + \delta\varphi - [(1 - \delta)\bar{b} - \hat{c} + \delta pf - (1 - \delta)\varphi]}{(1 - \delta)[\tilde{\sigma} - \delta p(\Delta - f) + \delta\varphi] + \delta[\tilde{\sigma}\underline{x} + (1 - \delta)\bar{b} - \hat{c} + \delta pf - (1 - \delta)\varphi]} \\ &= \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p\Delta + k - l - (1 - \delta)\bar{b} + \hat{c}}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \hat{c}] - \delta(1 - \delta)p\Delta + \delta pf}. \end{aligned}$$

Since this expression is linear in k , it is straightforward to maximize (11) and derive the optimal k , given l . As a start, note that:

$$\frac{\partial V^D}{\partial k} = \frac{\partial}{\partial k} (d-k) \frac{1-x}{1-\delta(1-x)} = \frac{d-k - \tilde{\sigma}(1-x) + \delta p \Delta - k + l + (1-\delta)\bar{b} - \hat{c}}{\tilde{\sigma}[1-\delta(1-x)] + \delta[(1-\delta)\bar{b} - \hat{c}] - \delta(1-\delta)p\Delta + \delta p f}, \quad (28)$$

which is increasing and convex in $p\Delta$. The first-order condition w.r.t. $k \geq 0$ gives (the second-order condition holds trivially):

$$(d-k) \frac{\partial}{\partial k} \left(\frac{1-x}{1-\delta(1-x)} \right) - \frac{1-x}{1-\delta(1-x)} \leq 0 \Leftrightarrow \quad (29)$$

$$d-k - [\tilde{\sigma}(1-x) - \delta p \Delta + k - l - (1-\delta)\bar{b} + \hat{c}] \leq 0, \quad (30)$$

with equality if $k > 0$, if the corresponding x is in (\underline{x}, \bar{x}) . With $\hat{c} = \underline{c}$ and $l = 0$, we arrive at (12).

Observation 3: If $x \rightarrow 1$, (29) requires $k \rightarrow d$.

We obtain the corner solution $x = \underline{x}$ if (30) is positive at the k ensuring $\theta_{kl}(\underline{x}) = 0$. From (24), we see that this is the k satisfying:

$$\begin{aligned} \theta_{kl}(\underline{x}) &= (1-\delta)\bar{b} - \hat{c} + \delta p \Delta \underline{x} + \delta p(1-\underline{x})f + (l-k)[1-\delta(1-\underline{x})] = 0 \Leftrightarrow \\ k &= l + \frac{1-\delta}{1-\delta(1-\underline{x})}\bar{b} - \frac{\hat{c}}{1-\delta(1-\underline{x})} + \frac{\delta p \Delta \underline{x}}{1-\delta(1-\underline{x})} + \frac{\delta p(1-\underline{x})f}{1-\delta(1-\underline{x})} \end{aligned}$$

At this k , (30) is indeed positive if $d \geq \bar{d}$, where

$$\begin{aligned} \bar{d} &\equiv l + 2\frac{1-\delta}{1-\delta(1-\underline{x})}\bar{b} - 2\frac{\hat{c}}{1-\delta(1-\underline{x})} + 2\frac{\delta p \Delta \underline{x}}{1-\delta(1-\underline{x})} + 2\frac{\delta p(1-\underline{x})f}{1-\delta(1-\underline{x})} \\ &\quad + \tilde{\sigma}(1-\underline{x}) - \delta p \Delta - (1-\delta)\bar{b} + \hat{c}. \end{aligned}$$

Observation 4: When $d \geq \bar{d}$, D pays so much that (A1) fails and $x = \underline{x}$. *QED*

Proof of Proposition 5:

The above best-response functions (30) and (27) already permit the other payer's decision. If we combine the two to solve for $k^* - l^*$, and combine that, in turn, with (26), then we obtain (16), given that we assume interior solutions for k^* and l^* . *QED*

Proof of Proposition 6:

First, notice that f has the same role as αk_R . If we set f , which is defined as $\hat{c} - \underline{c}$, equal to αk_R in (24), we obtain the expression for $\theta_R(x)$. With this, the proposition follows straightforwardly from the first-order conditions of the Lagrange problem (18). Part (iv) follows from the fact that payments to the public or the party increases P_t 's continuation value, conditional on x , and this reduces x_t . The final part of (iv) follows from Observation 2, above. *QED*

Proof of Proposition 7:

The proof follows from the reasoning in the text. *QED*

Proof of Proposition 8:

Note that we can write:

$$V_t^E = x_t (e - l_t) + (1 - x_t) \delta V^E, \text{ where}$$

$$V^E = \frac{(e - l) x}{1 - \delta + \delta x} \text{ and } \frac{\partial x_t}{\partial l_t} = \frac{\bar{x} - x}{\sigma} [1 - \delta (1 - x)].$$

Thus, the derivative of V_t^E w.r.t. l_t gives:

$$\frac{\partial V_t^E}{\partial l_t} = \frac{\bar{x} - x}{\sigma} [1 - \delta (1 - x)] (e - l_t - \delta V^E) - x_t,$$

which decreases in l_t , implying that the s.o.c. holds. When this derivative equals zero, the f.o.c. holds and it can be written as:

$$\frac{\bar{x} - x}{\sigma} [1 - \delta (1 - x)] (e - l_t - \delta V^E) = x_t \Leftrightarrow$$

$$[1 - \delta (1 - x)] (e - l_t) - \delta (e - l) x = \tilde{\sigma} x_t \quad (31)$$

$$= \tilde{\sigma} \underline{x} + (1 - \delta) \bar{b} - \hat{c} + \delta p \Delta x + \delta p (1 - x) f + (l_t - k_t) [1 - \delta (1 - x)]. \quad (32)$$

Define $\eta \equiv l - l_t$. Then, when E anticipates that $k_t = k$, and with (27) describing the equilibrium under commitment, l^* , (32) can be written as:

$$\eta [1 - \delta (1 - x)] + (1 - \delta) (e - l)$$

$$= (1 - \delta) (e - l^*) - (1 - \delta) (l^* - k^*) + \delta p (\Delta - f) x + (l_t - k_t) [1 - \delta (1 - x)] \Leftrightarrow$$

$$2\eta [1 - \delta (1 - x)] = 2(1 - \delta) (l_+ - l^*) - (1 - \delta) (k_t - k^*) + x \theta'_{kl}. \quad (33)$$

First, note that if $l_+ - l^* = k_t - k^* = 0$, the r.h.s. is positive iff $\theta'_{kl} > 0$ so, then, $l_t < l^*$. In other words, if the contributions k^* and l^* are expected, E is tempted to lobby less than l^* iff $\theta'_{kl} > 0$.

Second, in a stationary equilibrium, $\eta = 0$, so l can be written as:

$$l^M = l^* - \frac{k^* - k}{2} - \frac{x \theta'_{kl}}{2(1 - \delta)}.$$

If the right-hand side is negative when x and θ'_{kl} are evaluated at $l = 0$, $l^M = 0$, given the constraint $l \geq 0$. There is a unique equilibrium in Section 3.1 (when $k^* = k = 0$), in contrast to the situation in Section 3.2, because both x and θ'_{kl} increase in l . *QED*

Proof of Proposition 9:

Note that if we fix the future k (and thus the future x), we get:

$$\frac{\partial V_t^D}{\partial k_t} = \frac{\partial (1 - x_t)}{\partial k_t} (d - k_t + \delta V^D) - (1 - x_t), \text{ where} \quad (34)$$

$$\frac{\partial (1 - x_t)}{\partial k_t} = \frac{\bar{x} - x}{\sigma} [1 - \delta (1 - x)] \text{ and } V^D = (d - k) \frac{1 - x}{1 - \delta (1 - x)}.$$

Equalizing (34) to zero gives the f.o.c. (the s.o.c. clearly holds):

$$\frac{\bar{x} - \underline{x}}{\sigma} [1 - \delta(1 - x)] (d - k_t + \delta V^D) = 1 - x_t \Leftrightarrow \quad (35)$$

$$[1 - \delta(1 - x)] (d - k_t) + \delta(d - k)(1 - x) = \tilde{\sigma}(1 - x_t), \quad (36)$$

and, with (25), (36) becomes

$$\begin{aligned} & [1 - \delta(1 - x)] (d - k_t) + \delta(d - k)(1 - x) \\ &= \tilde{\sigma} \left(1 - \underline{x} - \frac{1}{\tilde{\sigma}} [(1 - \delta)\bar{b} - \widehat{c} + \delta p \Delta x + \delta p(1 - x)f + (l_t - k_t)[1 - \delta(1 - x)]] \right) \\ &= \tilde{\sigma}(1 - \underline{x}) - [(1 - \delta)\bar{b} - \widehat{c} + \delta p \Delta x + \delta p(1 - x)f + (l_t - k_t)[1 - \delta(1 - x)]] \Leftrightarrow \\ & (2k_t - d - l_t)[1 - \delta(1 - x)] \quad (37) \\ &= \delta(d - k)(1 - x) - [\tilde{\sigma}(1 - \underline{x}) - (1 - \delta)\bar{b} + \widehat{c}] + \delta p \Delta x + \delta p(1 - x)f. \end{aligned}$$

With $\lambda \equiv k_t - k$, and when (30) is substituted into the bracket on the r.h.s. of (37), we can rewrite this expression as follows:

$$\begin{aligned} & (2k_t - d - l_t)[1 - \delta(1 - x)] \\ &= \delta(d - k)(1 - x) - [(d - k^*) - (k^* - l^*) + \delta p \Delta] + \delta p \Delta x + \delta p(1 - x)f \Leftrightarrow \\ & 2\lambda[1 - \delta(1 - x)] = 2(k^* - k) - (l^* - l) - (1 - x(k))\theta'_{kl}. \end{aligned}$$

In the last equation, x and θ'_{kl} are written explicitly as functions of k . Given the constraint $k_t \geq 0$, the f.o.c. is also satisfied at $k_t = k = 0$ if:

$$-(l^* - l) - (1 - x(0))\theta'_{kl}(0) \leq 0,$$

so, when this condition holds, $k = 0$ also represents a pure-strategy MPE outcome.

It is possible to derive an explicit equation for k^M . From (36), note that $x - x_t = \lambda \frac{\bar{x} - \underline{x}}{\sigma} [1 - \delta(1 - x)]$, so (36) can be written as:

$$\begin{aligned} & [1 - \delta(1 - x)] (d - k_t) + \delta(d - k)(1 - x) = \tilde{\sigma}(1 - x_t) \Leftrightarrow \\ & [1 - \delta(1 - x)] (d - k - \lambda) + \delta(d - k)(1 - x) = \tilde{\sigma} \left(1 - x + \lambda \frac{\bar{x} - \underline{x}}{\sigma} [1 - \delta(1 - x)] \right) \\ &= \tilde{\sigma}(1 - x) + \lambda [1 - \delta(1 - x)] \Leftrightarrow \\ & (2\lambda + k - d)[1 - \delta(1 - x)] = [\delta(d - k) - \tilde{\sigma}](1 - x) \Leftrightarrow \\ & 2\lambda = (d - k) \left[1 + \delta \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p \Delta + k - l - (1 - \delta)\bar{b} + \widehat{c}}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \widehat{c}] - \delta p \Delta(1 - \delta) + \delta p f} \right] \\ & - \tilde{\sigma} \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p \Delta + k - l - (1 - \delta)\bar{b} + \widehat{c}}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \widehat{c}] - \delta p \Delta(1 - \delta) + \delta p f}, \end{aligned}$$

which gives

$$\begin{aligned}
& 2\lambda [\tilde{\sigma} [1 - \delta (1 - \underline{x})] + \delta [(1 - \delta) \bar{b} - \hat{c}] - \delta (1 - \delta) p\Delta + \delta pf] / \delta \\
& = (d - k) (k - l - p\Delta + pf + \tilde{\sigma}/\delta) \\
& - \frac{\tilde{\sigma}}{\delta} [\tilde{\sigma} (1 - \underline{x}) - \delta p\Delta + k - l - (1 - \delta) \bar{b} + \hat{c}],
\end{aligned} \tag{38}$$

where the right-hand side is hump-shaped and concave (and quadratic) in k . For $k_t = k$ (implying $\lambda = 0$) to constitute a stable stationary equilibrium, k must equal the largest k satisfying the above (and the following, rewritten) quadratic equation:

$$\begin{aligned}
& k^2 + k (2\tilde{\sigma}/\delta - p\Delta + pf - l - d) - d (\tilde{\sigma}/\delta - p\Delta + pf - l) + \\
& \frac{\tilde{\sigma}}{\delta} [\tilde{\sigma} (1 - \underline{x}) - \delta p\Delta - l - (1 - \delta) \bar{b} + \hat{c}] = 0.
\end{aligned}$$

The stable k is the largest k satisfying this equation, i.e.:

$$\begin{aligned}
k^M & = -\frac{2\tilde{\sigma}/\delta - p\Delta + pf - l - d}{2} + \frac{1}{2} \\
& \sqrt{\left(\frac{2\tilde{\sigma}}{\delta} - p\Delta + pf - l - d\right)^2 + 4d \left(\frac{\tilde{\sigma}}{\delta} - p\Delta + pf - l\right) - 4\frac{\tilde{\sigma}}{\delta} [\tilde{\sigma} (1 - \underline{x}) - \delta p\Delta - l - (1 - \delta) \bar{b} + \hat{c}]}
\end{aligned}$$

Since the r.h.s. of (38) is hump-shaped in k , there can be multiple stable equilibria: $k = 0$ is an equilibrium if the r.h.s. of (38) is negative at $k = 0$, i.e., if:

$$d(pf + \tilde{\sigma}/\delta - l - p\Delta) - \frac{\tilde{\sigma}}{\delta} [\tilde{\sigma} (1 - \underline{x}) - \delta p\Delta - l - (1 - \delta) \bar{b} + \hat{c}] < 0.$$

QED

Proof of Proposition 10:

In a stationary equilibrium, (36) and (31) give:

$$\begin{aligned}
& d - k^M = \tilde{\sigma} (1 - x) \text{ and } e - l^M = \tilde{\sigma} x / (1 - \delta), \text{ so:} \\
& k^M - l^M = d - e - \tilde{\sigma} (1 - x^M) + \tilde{\sigma} x^M / (1 - \delta) = d - e + \left(\frac{2 - \delta}{1 - \delta} x^M - 1\right) \tilde{\sigma}. \tag{39}
\end{aligned}$$

When the parties can commit, as in Propositions 3 and 4, we get the same expressions for $d - k$, $e - l$, and $k - l$, as in (39), except that $\tilde{\sigma}$ is replaced by $\tilde{\sigma} - (\delta p\Delta - \delta pf + \delta (l^* - k^*)) = \tilde{\sigma} - \theta^{*'}(x)$. This follows from Lemma 2, below. Thus:

$$\begin{aligned}
& k^* - l^* = d - e + \left(\frac{2 - \delta}{1 - \delta} x^* - 1\right) [\tilde{\sigma} - \theta^{*'}(x)] \\
& = d - e + \left(\frac{2 - \delta}{1 - \delta} x - 1\right) [\tilde{\sigma} - \theta^{*'}(x)] + \frac{2 - \delta}{1 - \delta} (x^* - x) [\tilde{\sigma} - \theta^{*'}(x)].
\end{aligned}$$

So, in both cases, $k - l$ increases in x , and since x increases in $k - l$, the two curves cross exactly once. (I.e., we do not have multiple equilibria.)

By combining the expression for $k^M - l^M$ and the expression for $k^* - l^*$, we get:

$$\begin{aligned} (k^M - l^M) - (k^* - l^*) &= \left(\frac{2 - \delta}{1 - \delta} x^M - 1 \right) \tilde{\sigma} - \left(\frac{2 - \delta}{1 - \delta} x^* - 1 \right) [\tilde{\sigma} - \theta^{*'}(x)] \Leftrightarrow \\ (k^M - l^M) - (k^* - l^*) + \frac{2 - \delta}{1 - \delta} \tilde{\sigma} (x^* - x^M) &= \left(\frac{2 - \delta}{1 - \delta} x^* - 1 \right) \theta^{*'}(x). \end{aligned} \quad (40)$$

Note that the two brackets on the l.h.s. have the same sign: $(k^M - l^M) > (k^* - l^*) \Leftrightarrow x^* > x$. Hence, both these equalities hold if the r.h.s. of (40) is positive, and both fails if the r.h.s. is negative. *QED*

Lemma 2: *Under commitments, we have*

$$\begin{aligned} d - k^* &= (1 - x^*) [\tilde{\sigma} - (\delta p \Delta - \delta p f + \delta (l^* - k^*))] \text{ and} \\ e - l^* &= \frac{x^*}{1 - \delta} [\tilde{\sigma} - (\delta p \Delta - \delta p f + \delta (l^* - k^*))]. \end{aligned}$$

Proof: As an alternative to the proof of Proposition 4, we can derive k^* from the following f.o.c.:

$$\begin{aligned} (d - k) \frac{\partial}{\partial k} \left(\frac{1 - x}{1 - \delta(1 - x)} \right) - \frac{1 - x}{1 - \delta(1 - x)} &= 0 \Leftrightarrow \\ (d - k) \frac{-1}{1 - \delta(1 - x)} \frac{\partial x}{\partial k} &= 1 - x \Leftrightarrow \\ \frac{d - k}{1 - \delta + \delta x} \frac{[1 - \delta(1 - x)]}{\tilde{\sigma} - (\delta p \Delta - \delta p f + \delta (l - k))} &= 1 - x \Leftrightarrow \\ \frac{d - k}{\tilde{\sigma} - (\delta p \Delta - \delta p f + \delta (l - k))} &= 1 - x. \end{aligned} \quad (41)$$

And, as an alternative to the proof of Proposition 3, l^* can be derived as follows:

$$\begin{aligned} (e - l) \frac{\partial}{\partial l} \left(\frac{x}{1 - \delta(1 - x)} \right) - \frac{x}{1 - \delta(1 - x)} &= 0 \Leftrightarrow \\ (e - l) \frac{1 - \delta}{[1 - \delta(1 - x)]} \frac{\partial x}{\partial l} &= x \Leftrightarrow \\ (e - l) \frac{1 - \delta}{\tilde{\sigma} - (\delta p \Delta - \delta p f + \delta (l - k))} &= x. \end{aligned} \quad (42)$$

QED

ONLINE APPENDIX A
ALTERNATIVE ASSUMPTIONS AND APPLICATIONS

A.1. *Optimal Conservation Targets under Budget Constraints*

Drawing on Section 4.1, we can investigate how the optimal target for the conservation funds depends on D 's budget and preferences (i.e, on d). Assume, for simplicity, that $l = 0$. The donor's continuation value is:

$$(d - K) \frac{1 - x}{1 - \delta(1 - x)}, \text{ where}$$

$$K = k + k_G + k_R.$$

It is easy to see that the second term ($\frac{1-x}{1-\delta(1-x)}$) is linear in k . (It was for that reason the expression for the optimal k was so simple to derive.) It is also easy to see that this second term is convex in k_G , and also in k_R if $p < 1$. Intuitively, the additional direct future conservation value associated with funding public goods, or party perks, makes it especially attractive for the president to conserve, particularly if also future conservation is likely (because the funds are large). This is the intuition for why a large budget, K , makes it more likely that it is optimal for D to earmark funds for party perks rather than letting the president decide, and for why it is more likely that D benefits from earmarking the funds for the public goods.

Proposition 11. *If K is D 's fixed budget, there exists thresholds K_1 , K_2 , and K_3 , such that:*

- (i) *D prefers to earmark the funds for the party, rather than letting the president have full discretion, if $K > K_1$,*
- (ii) *D prefers to earmark the funds for the public, rather than letting the president have full discretion, if $K > K_2$,*
- (iii) *D prefers to earmark the funds for the public, rather than the party, if $K > K_3$.*

When the budget K is optimally set by the donor, it is likely that a larger d makes it optimal to have a larger budget. It then follows that:

Corollary. *There exists thresholds d_1 , d_2 , and d_3 , such that:*

- (i) *D prefers to earmark the funds for the public, rather than the party, if $d > d_1$,*
- (ii) *D prefers to earmark the funds for the public, rather than letting the president have full discretion, if $d > d_2$,*
- (iii) *D prefers to earmark the funds for the party, rather than letting the president have full discretion, if $d > d_3$.*

So, if the donor is formed by a large coalition of countries, d is likely to be large and thus it is likely that the funds should be earmarked to public goods. Of course, as noted above, this requires D to build a reputation for earmarking the funds in this way. (At every time t , it is tempting for D to instead pay the president directly if $\alpha < 1$ and $\gamma < 1$.)

A.2. *Heterogeneous Parties and Elections*

Suppose there are two parties, A and B , and that A is more likely to win as long as the resource exists (i.e., $p^A < p^B$). Suppose there are no office rents (I will relax this assumption below).

Proposition 12. *The minority party exploits the most when it is in power (iff $\Delta > 0$):*

$$x^i = \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta p^i \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j}, \quad i \in \{A, B\} \Rightarrow$$

$$x^B - x^A = (p^B - p^A) \Delta \frac{\delta \left(\frac{\bar{x}-\underline{x}}{\sigma} \right)^2 [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^A p^B} \Rightarrow$$

$$x^B > x^A \text{ iff } p^B > p^A.$$

It also follows from this equation (see the proof in Appendix B) that less is exploited when the probability that the major party wins increases.

Proposition 13. *Expected exploitation is maximized when $p^i \rightarrow 1/2$ (iff $\Delta > 0$):*

$$(1 - p^i) x^i + p^i x^j = \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + 2 \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta (1 - p^i) p^i \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 (1 - p^i) p^i}.$$

Elections.—We can easily endogenize the winning probabilities. Suppose that the median voter prefers conservation ($(1-\delta)b < c$) and elects party i if the difference in continuation value, $V_i^\varphi - V_j^\varphi$, is larger than the popularity shock favoring party j and suppose this shock is i.i.d. uniformly and symmetrically distributed over time. Then, party i is more likely to win if $V_i^\varphi - V_j^\varphi$ is large, which holds if $x^j - x^i$ is large. Since $x^j > x^i$ if $p^j > p^i$, there can be multiple equilibria where a party receives less votes because the party exploits more, and the party exploits more because it is less likely to be in power later.

Proposition 14. *There are multiple equilibria where $p^i > p^j$ and $x^i > x^j$, $i \in \{A, B\}$. In equilibrium, the asymmetry $|p^i - p^j|$ increases in $\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta$:*

$$(1 - p^i) p^i = \frac{1 - 2\delta\Delta \left(\frac{\bar{x}-\underline{x}}{\sigma} \right)^2 [(1-\delta)\bar{b} - \underline{c}]}{\left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2}$$

Office rents.—Now, suppose R measures the rents for being in office, per se. Suppose, further, than if the resource is fully exploited, then $p^i = 1/2$, since then there is no longer any disagreement between the parties when it comes to this issue. If $p^B > 1/2$, party B faces an additional incentive to exploit: Not only will one then obtain the benefit b_p , but in addition the chance for office rents will be larger in the future. This effect is naturally strengthening B 's incentive to exploit. For the analogous reason, A 's incentive to exploit decreases (iff $\Delta > 0$), since A loses his electoral advantage once the resource is exploited.

Proposition 15. *Consider an equilibrium with $p^B > p^A$ and $x^B > x^A$. If the office rent R increases, x^B increases and x^A decreases, so polarization increases. As a consequence, p^B increases and p^A decreases.*

A.3. Postponing Reforms ($\Delta < 0$)

The above framework can shed light on several other situations besides resource extraction. As discussed in the Introduction, a larger body of literature analyzes macroeconomic policies in dynamic contexts. In some of these papers, the decision is whether to cut spending and stabilize debt (Alesina and Drazen, 1991) or to invest in state capacity (Besley and Persson, 2009; 2010). Stopping the game in this way is costly for a policymaker, and every government may hope that this cost will instead be paid by subsequent governments.

This situation fits the model except that now it is reasonable that $\Delta < 0$. The above equations hold also for this case, but the interpretations of the results will be different. When $\Delta < 0$, each president is more likely to stop the game (by completing the project of stabilizing debt, for example) if later governments are *less* likely to stop the game in this way. That is, $\partial\theta(x)/\partial x < 0$, and the multiplier is thus less than 1. This sign also eliminates the possibility of multiple equilibria, illustrated in Figure 1 (i-2).²³

Also for this application, it seems reasonable that stakeholders (domestic businesses) may lobby the president to postpone the action, while external stakeholders (such as the IMF) may try to persuade the government to act (and repay the debt). The above analyses of such payments continue to hold, but the differences between the long-term optimal payments (k^* and l^*) and the short-term (Markov-perfect) payments (k^M and l^M) change sign.

Corollary. *When $\partial\theta(x)/\partial x < 0$, the multiplier is less than 1 and both A and D prefer to commit to lower levels of future payments.*

For the donor (e.g., the IMF), the intuition is that it is beneficial to reduce the probability that future governments will act, so as to prompt the current government to act, instead. When the future arrives and no debt is repaid, however, the IMF is inclined to continue the effort by helping the government to repay the debt (this is the classic soft budget constraint).

The results from the previous subsection are also modified in interesting ways when $\Delta < 0$. In this case, each party hopes the other party ends the game, since that is costly. It is natural to assume, now, that the voters prefer to end the game (by completing the reform).

Corollary. *When $\Delta < 0$, the minor party B is less likely to act (by "completing a reform"). There are multiple equilibria in which $x^B < x^A$ and $p^B > p^A$ even though the parties are identical in other respects. If the office rent R increases, the two policies converge: x^B increases and x^A decreases.*

²³The conjectures discussed in Section 2.5 are also reversed: If $\Delta < 0$, the dominant party is more likely to end the game. When also the voters prefer to end the game, high office rents can motivate the minority party to adopt the opponent's policy (of ending the game), and vice versa, in order to eliminate its handicap in the election.

The intuition for the last statement is that because the issue gives A an electoral advantage (because A is more likely to end the game than B), then A 's incentive to complete the project is weakened but B 's is strengthened.

A.4. Convex Extraction Costs and Price Shocks: Interior Solutions

In this extension, I will show that quadratic extraction costs in the gradual-extraction model is isomorphic to a model with a uniformly distributed price on the part of the resource that is extracted. (I.e., this part generalizes the reasoning in Section 2.2.)

A Model with Stochastic Resource Prices.—Suppose c is the same for everyone, but that from b is subtracted a benefit-reduction ϵ_t , measuring a negative shock on the profit from logging (due to, for example, low resource prices in period t). Let ϵ_t be uniformly i.i.d. on $[0, \sigma_b]$. As before $b_p - b = \Delta$ is the additional benefit from exploitation for the party in power.

Let $V^P(x)$ be the continuation value in the future if the resource is conserved now. Anticipating $V^P(x)$, the president exploits if:

$$\begin{aligned} b_P - \epsilon_t &> c + \delta V^P(x) \Rightarrow \\ \epsilon_t &< \hat{\epsilon} \equiv b_P - c - \delta V^P(x), \end{aligned}$$

which holds with probability:

$$x_t^* = \Pr(\epsilon_t < \hat{\epsilon}) = \frac{\hat{\epsilon}}{\sigma_b} = \frac{1}{\sigma_b} [b_P - c - \delta V^P(x)]. \quad (43)$$

Given this threshold, we have that $\mathbf{E}(b_P - \epsilon_t \mid \epsilon_t < \hat{\epsilon}) = b_P - \hat{\epsilon}/2 = b_P - \sigma_b x/2$. Anticipating this, and with $\tilde{b} \equiv b + (1 - p)\Delta$, we have:

$$V^P(x) = \left(\tilde{b} - \sigma_b x/2 \right) x + (1 - x) (c + \delta V^P) = \frac{\left(\tilde{b} - \sigma_b x/2 \right) x + (1 - x) c}{1 - \delta(1 - x)}. \quad (44)$$

Substituted into (43), we get

$$x_t = \frac{1}{\sigma_b} \left[b_P - c - \delta \frac{\left(\tilde{b} - \sigma_b x/2 \right) x + (1 - x) c}{1 - \delta(1 - x)} \right].$$

A Model with Gradual Extraction and Convex Extraction Costs.—Suppose now that there are no shocks, but that x is the fraction of the resource that is extracted. The remaining stock of the resource next period is $S_{t+1} = (1 - x_t) S_t$, as in Section 2.2. Suppose, further, that the extraction cost is $\sigma_b S_t x_t^2/2$, given some parameter $\sigma_b > 0$. This cost function means that the marginal extraction costs increases in the fraction that is extracted. It is natural that, given x_t , the total cost may be proportional to S_t . With this, the continuation value per unit of the stock is exactly as in (44), and, anticipating V^P , the optimal extraction level

is

$$x_t^* = \arg \max_{x_t} \left(b_p x_t S_t - \sigma_b \frac{x_t^2}{2} S_t + (1 - x_t) S_t (c + \delta V^P(x)) \right) = \frac{1}{\sigma_b} [b_P - c - V^P(x)],$$

exactly as in (43).

Proposition 16. *The stochastic-price model and the convex-extraction-cost model are isomorphic:*

- (i) *The per-unit-of-stock continuation value is the same for both models.*
- (ii) *The optimal x is the same for both models.*
- (iii) *The assumption of uniformly distributed shock is analogous to the assumption of a quadratic extraction cost.*

Heterogeneous Parties.—This model generalizes the basic model, which restricted attention to a constant Δ (which had to be either positive or negative). Here, the optimal x is interior and thus x is perceived to be too small if x is small (as when $\Delta < 0$) and too large if x is large (as when $\Delta > 0$). In either case, $V^P(x)$ is less than it is at the optimal x .

It follows that if there are two parties with different preferences, then each party $i \in \{A, B\}$ extracts more when $p^i > 0$ than when $p^i = 0$, even if $b_P = b$.

To see this, note that if we henceforth assume $b_P = b$, but that parties have different b_i 's and c_i 's, then party i 's optimal x is (under commitment or with $p^i = 0$):

$$x^{i*} = \arg \max V_i^P = \frac{b_i - c_i}{\sigma_b}.$$

Thus, for any expected future $x \neq x^{i*}$, the continuation value is lower, $V_i^P(x) < V_i^P(x^{i*})$, and then (43) implies that i prefers $x_t > x^{i*}$ at any time t he is in power.

Proposition 17. *Suppose that parties prefer different x 's but preferences are the same whether the president's party is in vs. out of office (i.e., $b_{P,i} = b_i$). Then, each party $i \in \{A, B\}$ makes decisions s.t.*

$$x^i > x^{i*} \text{ iff } p^i > 0.$$

That is, both parties extract more when they fear to lose power – not because it is more beneficial to extract in office – but because each party perceives the resource to be mis-managed by the other party (whether that party is perceived to extract too much or too little), and thus it is less attractive to conserve the resource.

Now, suppose B is the party preferring the largest x : $x^{B*} > x^{A*}$. If D pays A to conserve more, V_B^P declines and (43) implies that x^B increases. In other words, payments (to A) in return for conservation can be counter-productive (since B may extract more).

On the other hand, if D pays B marginally to conserve, both x^B and x^A declines (x^A declines because V^A increases). This mechanism suggests that it may be less risky to pay B to conserve than paying A .

Corollary. *Suppose $x^{B*} > x^{A*}$. (i) If D pays A to conserve, x^B may increase. (ii) If D pays B (marginally) to conserve, both x^B and x^A are reduced.*

A.5. *Alternative Equilibria*

Above, the set of MPEs for the gradual-extraction model coincides with the set of SPEs for the probabilistic exploitation model (if only the outcome could be conserved). This claim holds also for the alternative model in Section A.4. However, when x represents gradual extraction (as a fraction of the stock) and S_t is the size of the remaining stock, then there are other SPEs in addition to the MPEs emphasized above.

As in other dynamic games with an infinite time horizon, there can be a large set of SPEs when the discount factor is large. For example, in the basic model, there may be an SPE in which every president sets $x_t = \underline{x}$ but, as soon as one president has deviated from this strategy, then we (re)turn to the MPE described in Section 2.4. It is easy to check that these strategies, and the outcome \underline{x} , can constitute an SPE if δ is above some threshold. If δ is lower than that threshold, then $x_t = \underline{x}$ cannot be guaranteed unless D makes $x_t = \underline{x}$ more attractive by compensating for conservation.

Formally, suppose V_E^P is the continuation value for the least conservation-friendly type in the cooperative equilibrium with low exploitation:

$$V_E^P = \tilde{b} \frac{\underline{x}}{1 - \delta(1 - \underline{x})} + \underline{c} \frac{1 - \underline{x}}{1 - \delta(1 - \underline{x})},$$

where $\tilde{b} \equiv pb + (1 - p)\bar{b}$, and let V_M^P be the same type's continuation value in the MPE:

$$V_M^P = \tilde{b} \frac{x}{1 - \delta(1 - x)} + \underline{c} \frac{1 - x}{1 - \delta(1 - x)} = \frac{(\tilde{b} - \underline{c}) \left[\bar{b} - \frac{\underline{c}}{1 - \delta} \right] + \underline{c} \left[\frac{\tilde{\sigma} - \delta p \Delta}{1 - \delta} \right]}{\tilde{\sigma} + \delta \left[\bar{b} - \frac{\underline{c}}{(1 - \delta)} \right] - \delta p \Delta}.$$

For $x = \underline{x}$ always to be an equilibrium, it must be attractive with $x = \underline{x}$ even for the least conservation-friendly president:

$$k + \underline{x}\bar{b} + (1 - \underline{x})(\underline{c} + \delta V_E^P) \geq \bar{x}\bar{b} + (1 - \bar{x})(\underline{c} + \delta V_M^P),$$

which holds iff k is sufficiently large.²⁴

Proposition 18. *When $x \in [\underline{x}, \bar{x}]$ represents gradual extraction, there exists an SPE outcome that guarantees $x_t = \underline{x} \forall t$, even if $k = 0$, iff $\delta \geq \bar{\delta}$. If δ falls below $\bar{\delta}$, $k > 0$ is necessary to sustain $x_t = \underline{x} \forall t$ as an SPE.*

However, note that if $\bar{x} = 1$, the condition becomes:

$$k + \underline{x}\bar{b} + (1 - \underline{x}) \left(\underline{c} + \delta \left[\tilde{b} \frac{\underline{x}}{1 - \delta(1 - \underline{x})} + \underline{c} \frac{1 - \underline{x}}{1 - \delta(1 - \underline{x})} \right] \right) \geq \bar{b},$$

but, when this inequality holds for some k , then $x = \underline{x}$ is also an MPE outcome for that same k . Thus, when $x = \underline{x}$, SPEs do not permit better equilibria than MPEs do.

²⁴Here, the role of k is to make a stream of environmentally friendly decisions self-enforcing, just like environmentally friendly technology made the climate agreement self-enforcing in the analysis by Harstad et al. (2019).

ONLINE APPENDIX B
PROOFS OF PROPOSITIONS 11-18

Proof of Proposition 11:

With the budget K , D 's objective is

$$(d - K) \frac{1 - x}{1 - \delta(1 - x)}, \text{ where}$$

$$K = k + k_G + k_R, \text{ and}$$

$$\begin{aligned} \frac{1 - x}{1 - \delta(1 - x)} &= \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p \Delta + k - l - (1 - \delta)\bar{b} + \hat{c}}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \hat{c}] - \delta(1 - \delta)p\Delta + \delta p f} \\ &= \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p \Delta + k - l - (1 - \delta)\bar{b} + \underline{c} + f}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \underline{c} - f] - \delta(1 - \delta)p\Delta + \delta p f} \\ &= \frac{\tilde{\sigma}(1 - \underline{x}) - \delta p \Delta + [K - k_G - k_R] - l - (1 - \delta)\bar{b} + \underline{c} + \gamma k_G + \alpha k_R}{\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \underline{c} - \gamma k_G - \alpha k_R] - \delta(1 - \delta)p\Delta + \delta p \alpha k_R}, \end{aligned}$$

when we substitute for the budget, i.e., $k = K - k_G - k_R$. The derivative w.r.t. k_G is:

$$\begin{aligned} & - (1 - \gamma) [\tilde{\sigma}[1 - \delta(1 - \underline{x})] + \delta[(1 - \delta)\bar{b} - \underline{c} - \gamma k_G - \alpha k_R] - \delta(1 - \delta)p\Delta + \delta p \alpha k_R] \\ & + \delta \gamma [\tilde{\sigma}(1 - \underline{x}) - \delta p \Delta + [K - k_G - k_R] - l - (1 - \delta)\bar{b} + \underline{c} + \gamma k_G + \alpha k_R], \end{aligned}$$

which is positive if K is sufficiently large.

The same qualitative statement can easily be obtained if we instead take the derivative w.r.t. k_R , and also if we set $k_R = K - k - k_G$ and then take the derivative w.r.t. k_G . *QED*

Proofs of Propositions 12-14:

The derivation of the best-response functions is analogous to the proof of Proposition 1. When we solve the two equations we get:

$$\begin{aligned} x^i &= \underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[\delta \Delta p^i x^j + (1 - \delta)\bar{b}^i - \underline{c}^i \right] \\ &= \underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^i - \underline{c}^i \right] + \frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^i x^j \\ &= \underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^i - \underline{c}^i \right] + \frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^i \left[\underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^j - \underline{c}^j \right] + \frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^j x^i \right] \Leftrightarrow \\ & x^i \left(1 - \left(\frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^i \right) \left(\frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^j \right) \right) \\ &= \underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^i - \underline{c}^i \right] + \frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^i \left[\underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^j - \underline{c}^j \right] \right] \Leftrightarrow \\ & x^i = \frac{\underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^i - \underline{c}^i \right] + \frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta p^i \left[\underline{x} + \frac{\bar{x} - \underline{x}}{\sigma} \left[(1 - \delta)\bar{b}^j - \underline{c}^j \right] \right]}{1 - \left(\frac{\bar{x} - \underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j}. \end{aligned}$$

If every $\bar{b}^i = \bar{b}$ and $\underline{c}^i = \underline{c}$, we get:

$$x^i = \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta p^i \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j},$$

so $x^i > x^j$ iff $p^i > p^j$, assuming $(1-\delta)\bar{b} > \underline{c}$.

Expected exploitation is:

$$\begin{aligned} & (1-p^i)x^i + p^i x^j \\ &= (1-p^i) \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta p^i \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j} \\ &+ p^i \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta p^j \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j} \\ &= (1-p^i) \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta p^i \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j} \\ &+ p^i \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta p^j \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j} \\ &= \frac{\left[\underline{x} + \frac{\bar{x}-\underline{x}}{\sigma} \left(1 + 2 \frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta (1-p^i)p^i \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 (1-p^i)p^i}, \end{aligned}$$

which is maximized at $p^i = 1 - p^i = 1/2$.

Difference in exploitation:

$$x^i - x^j = \frac{\left[\frac{\bar{x}-\underline{x}}{\sigma} \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta (p^i - (1-p^i)) \right) \right] [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 p^i p^j} = \frac{\delta \Delta \left(\frac{\bar{x}-\underline{x}}{\sigma} \right)^2 (2p^i - 1) [(1-\delta)\bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-\underline{x}}{\sigma} \delta \Delta \right)^2 (1-p^i)p^i}.$$

The median voter's utility is (V^φ is the *expected* continuation value if the resource has not been exploited):

$$\begin{aligned} V_i^\varphi &= b x^i + (1-x^i)(c + \delta V^\varphi) \\ V_i^\varphi - V_j^\varphi &= (x^j - x^i)(c + \delta V^\varphi - b). \end{aligned}$$

With probabilistic voting and symmetrically and uniformly distributed relative popularity shock, i wins with probability:

$$1 - p^i = \frac{1}{2} + \varsigma (x^j - x^i),$$

where ς is equal to the density of the shock multiplied by $(c + \delta V^\varphi - b)$. When we substitute

in for $(x^j - x^i)$, we get:

$$1 - p^i = \frac{1}{2} + \varsigma \frac{\delta \Delta \left(\frac{\bar{x}-x}{\sigma}\right)^2 (1 - 2p^i) [(1 - \delta) \bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-x}{\sigma} \delta \Delta\right)^2 (1 - p^i) p^i}, \text{ or}$$

$$p^j - p^i = 2\varsigma \frac{\delta \Delta \left(\frac{\bar{x}-x}{\sigma}\right)^2 (p^j - p^i) [(1 - \delta) \bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-x}{\sigma} \delta \Delta\right)^2 (1 - p^i) p^i}.$$

which pins down p^i , and thus the x 's. In particular, p^i is:

$$1 - 2p^i = 2 \frac{\delta \Delta \left(\frac{\bar{x}-x}{\sigma}\right)^2 (1 - 2p^i) [(1 - \delta) \bar{b} - \underline{c}]}{1 - \left(\frac{\bar{x}-x}{\sigma} \delta \Delta\right)^2 (1 - p^i) p^i}$$

$$1 - \left(\frac{\bar{x}-x}{\sigma} \delta \Delta\right)^2 (1 - p^i) p^i = 2\delta \Delta \left(\frac{\bar{x}-x}{\sigma}\right)^2 [(1 - \delta) \bar{b} - \underline{c}]$$

$$(1 - p^i) p^i = \frac{1 - 2\delta \Delta \left(\frac{\bar{x}-x}{\sigma}\right)^2 [(1 - \delta) \bar{b} - \underline{c}]}{\left(\frac{\bar{x}-x}{\sigma} \delta \Delta\right)^2},$$

which clearly gives multiple (two) equilibria, and there is more asymmetry (i.e., larger $|p^i - p^j|$) if the r.h.s. is small: I.e., if $\frac{\bar{x}-x}{\sigma} \delta \Delta$ and $(1 - \delta) \bar{b} - \underline{c}$ are large. *QED*

Proof of Proposition 15:

Let the office rent be R and suppose $p^B > p^A$. If the resource is exploited, however, the resource is no longer an electoral issue and thus suppose both probabilities are $1/2$ and each continuation value is $V_0^P = R/2 (1 - \delta)$.

P_t receives \bar{b} if he cuts now. Suppose that if P_t does not cut now, then his party will cut with probability y any later period it is in power, while the opposition exploits with probability x any period P_t 's party is not in power. With this, the current P_t 's continuation value at the beginning of any *later* period, $\tau > t$, is:

$$\begin{aligned} V^B &= (1 - p^B) R + (1 - p^B) x^B (\bar{b} + \delta V_0^P) + p^B x^A (b + \delta V_0^P) \\ &+ (1 - p^B) (1 - x^B) (\hat{c}_P + \delta V^P) + p^B (1 - x^A) (c_P + \delta V^P) \\ &= \frac{(1 - p^B) R + (1 - p^B) x^B (\bar{b} + \delta V_0^P) + p^B x^A (b + \delta V_0^P)}{1 - \delta (1 - p^B) (1 - x^B) - \delta p^B (1 - x^A)} \\ &+ \frac{(1 - p^B) (1 - x^B) \hat{c}_P + p^B (1 - x^A) c_P}{1 - \delta (1 - p^B) (1 - x^B) - \delta p^B (1 - x^A)}. \end{aligned}$$

P_t prefers to cut now if:

$$\begin{aligned}
 k + \widehat{c}_P + \delta V^B &< \bar{b} + l + \delta V_0^P \Leftrightarrow \\
 \delta \frac{(1-p^B)R + (1-p^B)x^B(\bar{b} + \delta V_0^P) + p^B x^A(b + \delta V_0^P)}{1 - \delta(1-p^B)(1-x^B) - \delta p^B(1-x^A)} \\
 + \delta \frac{(1-p^B)(1-x^B)\widehat{c}_P + p^B(1-x^A)c_P}{1 - \delta(1-p^B)(1-x^B) - \delta p^B(1-x^A)} \\
 &< \bar{b} + \delta V_0^P + l - k - \widehat{c}_P.
 \end{aligned}$$

With $\widehat{c}_P = c_P$, and $l = k = 0$, we get:

$$\begin{aligned}
 &\delta [(1-p^B)R + (1-p^B)(\bar{b} + \delta V_0^P) + p^B x^A(b + \delta V_0^P) + p^B(1-x^A)c_P] \\
 &< (\bar{b} + \delta V_0^P - \widehat{c}_P) [1 - \delta p^B(1-x^A)] \Rightarrow \\
 &\delta(1-p^B)R + [\delta - \delta p^B(1-x^A) - [1 - \delta p^B(1-x^A)]](\bar{b} + \delta V_0^P) - \delta p^B x^A \Delta \\
 &< -\widehat{c}_P [\delta p^B(1-x^A) + 1 - \delta p^B(1-x^A)] \Rightarrow \\
 &\delta(1-p^B)R - [1 - \delta](\bar{b} + \delta V_0^P) - \delta p^B x^A \Delta < -\widehat{c}_P \Rightarrow
 \end{aligned}$$

$$\begin{aligned}
 \theta_t &< \delta p^B x^A \Delta + [1 - \delta](\bar{b} + \delta V_0^P) - \delta(1-p^B)R - \underline{c} \Rightarrow \\
 \theta_t &< \delta p^B x^A \Delta + [1 - \delta] \left(\bar{b} + \delta \frac{R}{2(1-\delta)} \right) - \delta(1-p^B)R - \underline{c} \Rightarrow \\
 \theta_t &< \delta p^B x^A \Delta + [1 - \delta]\bar{b} + \delta \left(\frac{1}{2} - (1-p^B) \right) R - \underline{c} \Rightarrow \\
 \theta_t &< \delta p^B x^A \Delta + \delta \left(p^B - \frac{1}{2} \right) R + [1 - \delta]\bar{b} - \underline{c}.
 \end{aligned}$$

So, the minor (major) party becomes more (less) likely to exploit (regardless of the sign of Δ).

The derivation of the equilibrium p^i is similar to the previous proof. Thus, the larger polarization increases the difference in p^i , strengthening the polarization in x^i , etc. *QED*

Proofs of Propositions 16-18:

These proofs are in the text. *QED*
